REORGANIZATION OF INDUSTRIAL MICROBIOLOGICAL RESEARCH IN BRITAIN

THE Council for Scientific and Industrial Research has been considering certain aspects of the organization and support of microbiological research which is at present being carried out at the Water Pollution Research Laboratory, the National Chemical Laboratory, the Ditton Laboratory and the Torry Research Station at Aberdeen. The Council believes that an industrial microbiological team is able to do the best and most effective work when it operates within a research laboratory concerned with the technology served by the team. This is a point of view with which one must agree where industrial research is concerned, and in the present case it is well exemplified by the microbiological research now being undertaken in the Water Pollution Research Laboratory and the food research laboratories.

Although the Microbiology Group at the National Chemical Laboratory, numbering less than twenty, has undoubtedly done good work, the Council considers that the Group is not appropriately placed there; and therefore, apart from those working on the corrosion of metals, the chemical groups in that Laboratory do not benefit from the work of the microbiologists and, possibly, *vice versa*. So the Council believes that microbiological research work of the kind being done at the National Chemical Laboratory, apart from that concerned with the corrosion of metals, would in general be most effectively carried out in some university departments; and it is proposed to encourage support of such work within the universities by means of financial aid.

As a result of this, the Council is aiming at gradually dispersing the Microbiology Group now working at the National Chemical Laboratory. It is suggested that in future the work should be carried out as follows: (1) the Department of Scientific and Industrial Research will continue to maintain the National Collection of Industrial Bacteria, though it should go to the Torry Research Station, Aberdeen, where there is already a comparable collection of marine bacteria; (2) the microbiological work concerned with the corrosion of metals will be retained at the National Chemical Laboratory and expanded there; (3) the fundamental work on sulphur bacteria, at present being done at the National Chemical Laboratory, will end, though allied work, if justified, may be supported at a university; (4) fundamental work on the microbial formation of methane can be carried out at a university. The applied research covered by (3) and (4) is within the field of activity of the Water Pollution Research Laboratory, where any further necessary work in this connexion will be done.

The views of the Microbiology Committee of the Chemistry Research Board were made known fully to the Board itself, the Secretary of the Department of Scientific and Industrial Research and the Review Committee of the Council for Scientific and Industrial Research and, through the last-named, the Steering Committee of the National Chemical Laboratory and the Council. As a result, it is intended that the staff of the Microbiology Group at present working at the National Chemical Laboratory will be disbanded as such: the National Collection of Industrial Bacteria together with some workers will go to the Torry Research Station; some work will be transferred to the Water Pollution Laboratory; other workers will remain at the National Chemical Laboratory.

This proposal, which involves the division and dispersal of certain industrial microbiological research, and especially the removal of the National Collection, from the National Chemical Laboratory has not met with general approval, which is, perhaps, to be expected. Indeed, some microbiologists and others view the proposal with concern and are hostile to the idea of its being carried out before further inquiries have been made and the opinions of other scientists, especially microbiologists, sought. For example, the Institution of Professional Civil Servants and the Institute of Biology consider that the decisions being contemplated by the Council of Scientific and Industrial Research are to be deplored on both economic and scientific grounds. Moreover, they point out that there is no microbiologist on the Council, and they claim that, since the recommendation was made without the Microbiological Research Sub-Committee having been consulted, then this was done before proper advice was sought.

Mr. Stanley Mayne, general secretary of the Institution of Professional Civil Servants, believes that the existence of the present Microbiology Group in association with the National Collection of Industrial Bacteria is of considerable importance to many industrial concerns, as exemplified by the number of inquiries that are made. Nevertheless, in spite of Mr. Mayne's claim, it does not seem feasible that the work of dealing which such inquiries as are made or are likely to be made will become impossible if industrial microbiological research is distributed over a number of establishments. Much other closely connected scientific work is farmed out to different centres, both government and university, yet it does not appear to suffer in consequence. In fact, too much centralization and concentration can be a bad thing.

In a statement issued jointly by the Institution of Professional Civil Servants and the Institute of Biology on December 15, the main criticism was that advice had not been obtained from those most competent to judge before an important move was announced by the Research Council. Be that as it may, as already stated, certain authorities were advised beforehand, and, in any event, it does not follow that the decision is a bad one, especially if the main objective of those responsible for making it was the advancement of microbiological research for the benefit of the nation in general and industry in particular.

The joint statement claims that the disbanding of the Microbiological Group at the National Chemical Laboratory is ill-advised and, if implemented, will damage the national economy, for "its function cannot satisfactorily be discharged by any other body". This criticism seems premature, especially in view of the future arrangements for microbiological research being contemplated by the Council for Scientific and Industrial Research. The views expressed by the Council do not imply that microbiological research will be abandoned altogether; neither is it suggested that the work now being done will be handed over to an incompetent body. It appears that the move aims at so dispersing the Group that each new subdivision will find itself working in the most appropriate and advantageous environment.

It certainly seems a pity that the National Collection of Industrial Bacteria should be separated from the research unit as a whole; though some microbiologists will no doubt still be in direct association with it. In any event, if there is to be dispersal, then the Council has no choice other than to recommend the removal of the Collection to a place where it is of maximum service to science and industry; if, as is suggested, only the microbiological work on metal corrosion is to remain at the National Chemical Laboratory, then there seems little justification for the Collection remaining where it is. Most type collections and other national collections are inevitably centred at one, or just a few, places, in spite of the fact that cognate research may be very widely dispersed. It is difficult to see how this can be avoided. As the joint statement issued by the Institution of Professional Civil Servants and the Institute of Biology points out, removal of the Collection to Aberdeen might prove inconvenient, especially since, as the tatement claims, the majority of requests for technical help, the supply of cultures and the checking of purity come from the south of Britain. Moreover, visitors from abroad would probably find the siting of the Collection at Aberdeen somewhat of a nuisance. Apart from this, however, if the Collection is to be moved at all, Torry Research Station appears to be a very appropriate institution. The joint statement suggests that the Microbiology Group should either stay where it is or, if it is to be transferred out of the Department of Scientific and Industrial Research, it should be linked with the Microbiology Research Establishment of the Ministry of Supply at Porton. But the Council's statement says that if it goes to the Torry Research Station, the National Collection will still be maintained by the Department of Scientific and Industrial Research. Movement to Porton would bring the National Collection and its personnel in touch with medical instead of marine biological research, so, apart from difference in geographical site, the suggested move to Porton as opposed to Aberdeen seems to have little to recommend it.

The Institution of Professional Civil Servants and the Institute of Biology have made it quite clear that they deplore the splitting up of the present Group, and suggest that it should be established as a self-contained entity within the Department of Scientific and Industrial Research. Although there is much to be said in favour of this, the Council for Scientific and Industrial Research has also much in its favour in suggesting that microbiologists should work in a research laboratory most closely connected with the technology involved: this latter proposal must inevitably lead to a certain amount of farming out of the work. There is certainly much to be said for fundamental investigations of sulphur bacteria and the microbial formation of methane and, indeed, other aspects of microbiology, being supported by and in certain universities. Indeed, the Institution of Professional Civil Servants and the Institute of Biology concur with this proposal. The selected universities would offer certain biological and other facilities not to be found elsewhere. Such a development would seem to follow closely along the lines of policy adopted by the Australian Commonwealth Scientific and Industrial Research Organization, under the auspices and financial support of which varying scientific and industrial research laboratories are actually situated on the campuses of every university in Australia.

Other aspects of the case have, so far as we are aware, not been mentioned; for example, possible domestic problems and probably upheavals due to personnel being moved from the south of England to Aberdeen and the longer distances to be travelled in order to attend most conferences and meetings of learned societies, etc. But if the move is deemed of real advantage to the development of microbiological research, such obstacles must be accepted and overcome.

Obviously there is a schism in opinion concerning this case; and there is much to be said in favour of the proposal and against it. It can be taken for granted, however, that the Council for Scientific and Industrial Research delved deeply into the various aspects of the case before advising the splitting up of the Microbiology Group at the National Chemical Laboratory; so it will be a matter of time before judgment can be brought to bear on the proposal, if carried out. On the face of it, despite the disadvantages involved and inconveniences incurred, the distribution envisaged by the Council might well contribute to the advancement and advantage of industrial microbiology. The merits of division and dispersal may outweigh the demerits of disruption to the benefit of fundamental and applied microbiological research.

PROFESSIONAL METEOROLOGY AND EVERYDAY NEEDS

Everyday Meteorology

By Prof. A. Austin Miller and M. Parry. Pp. 270 + 22 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1958.) 30*s.* net.

Farming Weather

By L. P. Smith. (Nelson's Agriculture Series.) Pp. ix + 208 + 8 plates. (Edinburgh and London: Thomas Nelson and Sons, Ltd., 1958.) 15*s.* net.

BRITISH people are notorious for using their weather as a conversational gambit and as an alibi for Latin holidays. This combination of naïve intolerance and bemused escapism is reflected in the startling fact that the Meteorological Office is run, quoting Prof. A. A. Miller, "on a total annual budget of little more than the cost of a single modern bomber". Moreover, the proportion of this pittance allocated to specialized weather forecasting and advisory services, for example, for farmers and growers, is small compared, for example, with that devoted to upper-air research. The current preoccupation of our mathematical meteorologists with the physics of the atmosphere and the traditional restriction of Dunstable to sweepingly generalized forecasts marketed afterwards in newspapers and on television screens has perpetuated our habitual neglect of applied meteorology in terms of our everyday needs.

It is not surprising that, of the two volumes under review, one has been written by two geographers pledged to teach the weather not only *per se* but also in relation to society, and the other by a meteorologist pledged to direct weather advice to farmers and growers. Both books achieve an easy, readable style.

"Everyday Meteorology" deals with the origin and collection of weather data, the causes of weather, and the significance of frontal zones and air masses in the atmospheric circulation. Local and world types of weather are then described and finally some problems of weather forecasting, of 'living with' the weather and of 'harnessing' the weather, are discussed. Attempts at three-dimensional representation of weather systems are, unfortunately, few and in two instances quite misleading. In Figs. 38 and 39 upper winds relating to horizontal profiles are inserted on vertical cross-sections through frontal systems. The impression given in the second diagram is of a wind blowing down towards the Earth's surface through a large cumulus cloud. Parts of Chapter 9 are conspicuously inadequate in reference to soil climate, the growing season and land aspect. "A soil containing much water" is not necessarily "a clay soil" (p. 192), and the optimum insolation slope varies with the time of year between south-west and south-east (p. 197). These and other minor omissions and inconsistencies tend to detract from what is otherwise an attractively compiled work which renders accessible to the layman many meteorological ideas which might otherwise be beyond him.

"Farming Weather" aims at a particular section of the popular market. It presents a digestible and comprehensive survey of weather elements and factors and weather forecasting as they affect agriculture. The lack of precise recommendations to farmers on coping with weather hazards may be criticized by some. It should be stressed, however, that every farm, indeed every field, may require different weather advice because of small-scale variations in land morphology, soil conditions and associated micro-climates. Generalized advice, even for a local district, may be relatively useless. Adequate consultation of L. P. Smith's book should enable the farmer, or grower, to plan his programmes so as to anticipate certain weather hazards and accommodate them when they occur.

Professional meteorology would benefit by devoting more effort than heretofore to the applied problems so ably discussed in these two volumes. "Meteorology without Mathematics" may be regarded as impracticable and futile by the meteorologists, but mathematics without a morphological approach to weather study seems unlikely to provide us with a properly trained and localized advisory weather service.

JAMES A. TAYLOR

THE LIVING MOLLUSC

Molluscs

By Dr. J. E. Morton. Pp. 232. (London: Hutchinson and Co. (Publishers), Ltd., 1958.) 10*s.* 6*d.* net.

ALTHOUGH Dr. J. E. Morton states that there has been no general book on malacology written in Britain for forty-five years and so claims comparison with B. B. Woodward's brief "Life of the Mollusca", his book bears comparison better with Pelseneer's "Mollusca" published in 1906. Of necessity both much shorter and far less fully illustrated, yet it marks a notable stage in the growth of knowledge concerning the most structurally diverse of the invertebrate phyla. Pelseneer's volume represented the culmination of a notable period of comparative anatomy; it left the stage set for elucidation of the function of organs there so clearly described.

Dr. Morton's book represents the first comprehensive attempt, probably in any language, to summarize what has more recently been discovered about the function and significance of these organs, adding up in many cases to a very full understanding of the mode of life of the animals possessing them. He is particularly well qualified to deal with such matters by the beauty of his research and the distinction of his writing. Thus we read that "If pulmonates lack the structural variety shown by opisthobranchs, this is because they have made a much more subtle use of physiological adaptations", that the Gastropoda are a "living museum of adaptive morphology, nearly every family having some distinctive pattern to show", that nudibranchs are "the most colourful and extravagant of all gastropods", that "cephalopods are organized upon a more stereotyped pattern than gastropods or lamellibranchs; but this is a pattern of high success". He surmises that the extinct ammonoids "could make leisured saunters".

There is much to praise in this book and for any student of the Mollusca, as I have found, to learn from it. The restriction on length has made possible a price well within the range of all, amateur, student or professional zoologist, interested in malacology. It is, however, unfortunate that there is so little space and so indifferent a printing surface for the text-figures at which the author excels.

All this is not to say there is not matter for criticism. The impression is given that the bivalves possess a 'two-piece' shell, whereas the ligament is an integral part of the shell. Those who study oysters will be surprised to discover that at no stage is there a foot or a byssus gland, also that the adult may "break free". Although classification of the bivalves is far from satisfactory, matters are not improved by employing that of Douvillé.

C. M. YONGE

RESPONSES OF INVERTEBRATES

An Introduction to the Behaviour of Invertebrates

By Dr. J. D. Carthy. Pp. xi+380+4 plates. (London: George Allen and Unwin, Ltd., 1958.) 45*s*. net.

HERE is a useful summary of a large volume of literature on some responses of invertebrates to experimental stimulation. It is not, therefore, a textbook of behaviour, which is a larger subject including spontaneous activities, memory and central control mechanisms. There are chapters on the responses to stimulation in each of the main sensory modalities, including humidity changes and the contact chemical sense, in addition to those more familiar from our own experience. The final chapter, on whole patterns of behaviour, is disappointing, since the behaviourist approach and that of the neurologist are both excluded, leaving an account of the reactions to combined stimuli.

The coverage is excellent. The recent literature is summarized together with the old, but in some instances the necessary re-interpretations are not forthcoming. First, for example, in this decade a number of workers have shown that the angle of light acceptance of an ommatidium is wide compared with the interommatidial angle. Much of the earlier work on visual acuity and form vision by the apposition compound eye must now be attributed to post-retinal mechanisms. For a longer period it has been known that the principal physiological responses of many eyes change with time, and, in particular, some rapidly moving diurnal insects have little but an 'on' and an 'off' response. Form vision must then depend on relative movement of the eye and the object, and again must be attributed to post-retinal integration. Hassenstein's analysis of the *Wechselfolge* of *Chlorophanus* is an example of the new approach to this mechanism. Secondly, a most important theory of the relation between spontaneous movements and the responses to stimuli is that of von Holst; this is barely mentioned under the name re-afferentation, but not explained. Recent results from the Tübingen school demonstrate the explanatory value of these concepts in this field, and they deserve a better treatment.

In my own special field the literature summary is accurate, a judgment which can probably be extended to the remainder. The difficulty is not the labour of being acquainted with the material; it is the comprehension of its relation to the main body of knowledge. The solution of this problem distinguishes a synthesis from a compilation.

However, this is mild criticism. The book represents the painstaking and useful labour of summarizing a vast, diffuse and unsatisfactory field of zoology. The responses of whole animals to the somewhat artificial circumstances required by experimental analysis are notoriously difficult to interpret. Often a particular species is studied by only one author, so that comparisons are difficult and may not be valid. The experiments must often be made statistically with a large number of animals so that the mechanism within an individual is not easily approachable. This brings me to the final point. The introduction of delicate electrophysiological methods for the analysis of the actual performance of sense organs as transducers has led to a quiet revolution in our appreciation of the various parameters of a stimulus which can possibly be of importance to the animal. The problem of the origin of the integrated response is thereby usually pushed back into the central nervous system, but at least an advance is made. Neither this book, nor its predecessors, claims to synthesize this more recent neurophysiological analytical approach with the 'behaviour' of the whole animals. Perhaps the effort is doomed to frustration for a long time to come.

G. A. Horridge

FACT AND VALUE IN THE SOCIAL SCIENCES

Value in Social Theory

A Selection of Essays on Methodology. By Gunnar Myrdal. (International Library of Sociology and Social Reconstruction.) Pp. xlvi+269. (London: Routledge and Kegan Paul, Ltd., 1958.) 32*s*. net.

IN this book, Dr. Myrdal faces a simple but at the same time unsolved problem which has overshadowed the social sciences since their inception, namely, the relation between statements of fact and statements of value. As an economist, he found himself in his earlier days compelled to reject the solution of the "welfare economists"; in later years he was equally repelled by the "naïve empiricism" of the American institutional school, with the result that the value problem has come to be a "major preoccupation" for him, and questions of methodology have been for many years one of his continuing interests.

Dr. Myrdal's position at the present time is directly dependent on an acceptance and development of the view that 'objective' values cannot be established and known by scientific processes; subjective evaluations can be observed and analysed, but their validity and their significance for social theory only arise out of their acceptance by specific individuals and groups. In consequence, when Dr. Myrdal produced his great survey of race relations in the United States, "The American Dilemma", he made his value premises explicit, and based them so far as possible on observation. He made no attempt to argue that they could be incorporated in a body of fact and doctrine created by the research itself. He now concludes in the present book that valuations are necessary in all scientific work, and that "the final solution of the value problem in economic and in the social sciences generally must . . . be to set up a method by which human valuations are rationally and openly introduced into theoretical and practical research to give it direction and purpose to make it both unbiased and relevant to life". No research can, therefore, be *wertfrei*.

This is the point at which Dr. Myrdal leaves the argument in his "Postscript". It may be pointed out, however, that it is somewhat paradoxical to speak of the 'introduction' of values into research in this way because the very nature of science as a human activity is dependent on the logical presupposition that it should be unbiased. Moreover, as Mr. Streeten points out in the introduction to Dr. Myrdal's essays, the analysis and public discussion of beliefs and valuations tend to produce changes in them, and scientific inquiry thus plays its part in their formation. There is thus a connexion between fact and value, to this extent at least. If, however, it must be concluded that the social sciences cannot be 'objective' in Max Weber's sense because the connexion is not a logical one, there is nevertheless a limited area within which their explanation of man's behaviour is scientific, because, as Dr. Myrdal puts it, "there *is* a great deal of practically mechanistic causation in human life"; in particular, resistances to social change are "enormous", and the tendency for social phenomena to repeat themselves is correspondingly great. The true paradox in the social sciences which lies at the end of the Myrdal–Streeten argument is then that as the deeper understanding of social phenomena makes it possible to free them from the operation of 'mechanistic causation' in some measure, the social sciences must be supposed to contain within them, to the same extent, the seeds of their own destruction.

T. S. Simey

BIOCHEMISTRY IN MEDICINE

Advances in Clinical Chemistry

Vol. 1. Edited by Harry Sobotka and C. P. Stewart. Pp. xi + 398. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1958.) 12 dollars.

While most aspects of biochemistry have been adequately covered in many recent review journals, clinical chemistry has featured in the literature of recent years more in the form of new outlets for original papers and in a spate of fairly elementary texts. The present volume is therefore to be welcomed, since it is the first of a series in which selected topics will be reviewed thoroughly and authoritatively by experts who are actively working in the field which they describe. The authorship of this first volume is thoroughly international in composition; of the nine authors five are in Europe, three in America and one in Australia, while the two editors live in New York and Edinburgh respectively.

Any publication dealing with clinical chemistry is liable to become a mere compendium of methods. While methods feature very prominently, and rightly so, in this book, their appearance is balanced by an equally exhaustive discussion of what the editors term "the fundamental biochemical abnormalities which underlie disease". The choice of subjects has been very skilfully made to give a wide coverage of problems of topical interest. Thus the chapter by Wróblewski on the clinical significance of transaminase activities in serum is a welcome reminder that this enzyme is of interest in several conditions other than coronary thrombosis. The topical subject of 5-hydroxytryptamine and related compounds is covered by Dalgleish in a survey which differs from other recent reviews in being predominantly biochemical rather than pharmacological. Thyroid function is dealt with in Chaney's chapter on the analytically complex problem of the determination of protein-bound iodine and in Silver's contribution on plasma-levels of iodine-131. Plasma iron is competently dealt with by Ramsay. Two chapters which are essentially methodological, but which will be welcomed for their detailed and critical treatment of their subjects, are Neher's review of the determination of individual adrenocortical steroids and Owen's section on paper electrophoresis of proteins. Josephson contributes a brief but useful chapter on the composition of body fluids in childhood, and in collaboration with Ek also discusses the assessment of the tubular function of the kidneys.

Without attempting to detract from the value of the book, I would like to express an objection to the term 'clinical chemistry'. The subject so named, unless it be regarded merely as a technical exercise in chemical analysis, is essentially a division of the wider discipline of biochemistry in which biochemical principles are applied to the scientific study of disease in the hospital laboratory. While 'clinical chemistry' is certainly preferable to the alternative term 'chemical pathology', the most appropriate title is undoubtedly 'clinical biochemistry' or 'pathological biochemistry'.

J. N. Davidson

THE COLOURS OF DOGS

The Inheritance of Coat Color in Dogs

By Clarence C. Little. Pp. xiii + 194. (Ithaca, N.Y.: Comstock Publishing Associates, Cornell University Press; London: Constable and Co., Ltd., 1957.) 34*s*. net.

Most scientific breeders and geneticists will already know Dr. C. C. Little's book, which is making its appearance here under an English imprint. It gives the results of many years of research at Bar Harbor and in the author's own dog colony into the inheritance of the coat-colour patterns of most of the commercially important breeds of dog. In all, ten loci, some with several alleles, are discussed, and 4,100 pups of twenty-eight breeds have been raised in the laboratory colony—the rest of the results have come from co-operating breeders, through the American Kennel Club. This successful co-operation, which seems to have been very critically carried out, is one of the most interesting features of the study. Genetics are not the only field in which use could be made of the large number of dogs bred annually—longevity studies and surveys of the incidence of tumours have recently been attempted for various breeds, and although colour-scoring places a less exacting demand on those breeders who co-operate, the scale of Dr. Little's support is encouraging as an index of what could be done with this otherwise wasted biological information.

Breeders themselves stand to gain from the results of the study; the author has attempted to accommodate them, in a book directed chiefly to professional geneticists, and secondarily, perhaps, to veterinarians, by including a short refresher chapter on the mechanisms and terminology of inheritance, but this will only make his findings clearly intelligible to non-biological readers if they have a reasonable prior knowledge of genetics.

The results are concisely presented, first by loci and then by breeds. It is difficult for anyone not in the field to criticize the detailed conclusions reached. For the generality, one of the most useful items is a summary list of twenty-one breed- and colour-types where the genes represented are known with reasonable certainty. Little considers that 'true' albinism, with complete absence of skin pigment and with pink eyes, probably does occur in dogs, and that the 'blue-eyed' albino dogs and cats mentioned by Burns arise by a different mechanism. The effects of various modifiers upon the extent of pigment patches are well illustrated by drawings. Cases of supposed red-black somatic mutation in cocker spaniels are discussed: here as elsewhere the book is a provocation to the pigment chemist to find out the nature of the differences induced genetically between adjacent skin areas. It sticks strictly to its last, however: there is no general discussion of pigment epigenetics, and only incidental treatment of the problem of analogy between canine and other mammalian pigmentation genes; the substance of Dr. Little's recent and authoritative review of coat-colour genes in rodents and carnivores would be a useful additional chapter for future editions without making the book overlarge, and would widen its use for reference purposes. It is already a valuable standard work, and a tribute to the patience of its author which only those of his colleagues who work with the longer-lived mammals will fully appreciate. ALEX COMFORT

FLORA OF WEST AFRICA

Flora of West Tropical Africa
The British West African Territories, Libreria, The French and Portuguese Territories South of Latitude 18° N. to Lake Chad, and Fernando Po. By Dr. J. Hutchinson and Dr. J. M. Dalziel. Second edition revised by R. W. J. Keay. Vol. 1, Part 2. Pp. ii+297–828. (London: Crown Agents for Oversea Governments and Administrations, 1958.) 55*s.*

SCIENCE, fortunately, need not always wait on politics, and for thirty years the essential unity of the Upper Guinea region of Africa has been recognized and provided for by an excellent "Flora". It is not without interest to trace the historical background.

During the middle part of last century large collections of dried plants (herbarium specimens) began to arrive at Kew from what was then the British Empire, and Sir William Hooker, followed by his son Sir Joseph Hooker, initiated and undertook the vast project of providing "Floras" of these territories. The four major works, which started publication in 1860, were, in chronological order: "Flora Capensis", "Flora Australiensis", "Flora of Tropical Africa" and "Flora of British India". Of these the "Flora of Tropical Africa" (Vol. 1, published in 1868) was by far the least satisfactory for, with a few exceptions, only the periphery of the area was well known, and the earlier volumes often contained no more than about 10 per cent of the species now known to science. In the later decades of the nineteenth and the earlier decades of the twentieth centuries German botanists, inspired by Adolf Engler and encouraged by the political climate of German imperial expansion in Africa, did a vast amount of botanical work on tropical Africa, often without very close co-operation with similar work at Kew and the British Museum. By the 1920's the taxonomy of the flora of tropical Africa was in real confusion, and it was realized at Kew that a solution had to be found. Whether it would have been better to start a new edition of the "Flora of Tropical Africa" (the first edition of which has not been entirely completed to this day) is a matter of opinion, but the decision was taken, probably rightly, to start a new series of African regional "Floras". With institutional and, indeed, international co-operation, botanical work on Africa south of the Sahara has proceeded along that course with a fairly satisfactory regional division of the territory, leaving, however, a few unfortunate lacunae, of which the French Cameroons – French Congo region is the worst.

This brief historical summary is necessary to see the "Flora of West Tropical Africa" in perspective. It was the first of this new series of regional floras but differed fundamentally, in many respects, both from its aged parent and from its later successors ("Flore du Congo Belge", now well advanced; "Flora of East Tropical Africa", in course of publication; and "Flora Zambesiaca", in gestation). The original edition was initiated by Sir Arthur Hill, then director of Kew, financed by the British West African Governments, entrusted to Mr. (now Dr.) J. Hutchinson and the late Dr. J. M. Dalziel and completed over the period 1927–36. This represented very rapid work, and speed of production and conciseness were two of its main features. Synonymy, references and descriptions were cut to a minimum; but there were rather elaborate keys containing descriptive elements and the illustrations were generous. The arrangement of the families departed considerably from Bentham and Hooker traditions by following Hutchinson's own ideas on classification—usually, though not invariably, an improvement on the older one.

The work was at the time the only large-scale modern "Flora" of tropical Africa available and was in great demand not only in the territories for which it was intended but also throughout Africa, providing, often enough, the means for the field-botanist to achieve at least generic determinations anywhere in Africa south of the Sahara. It is not surprising that the first edition soon sold out, and it is gratifying that Kew has been able to undertake a much-needed revision and second edition.

This second edition was entrusted to Mr. R. W. J. Keay, of the Department of Forest Research, Nigeria, assisted by Mr. F. N. Hepper and several other members of the Kew staff. Keay, with an excellent knowledge of the plants obtained in the field, most unusually joined with an admirably balanced taxonomic judgment, has made a magnificent job of it, correcting the many errors which had not unnaturally been discovered with the passage of time in the original work and reorganizing some portions completely, although keeping the original format and reconciling so far as possible the conflicting claims of accuracy and speed. It is a splendid work of the highest value and importance taxonomically, ecologically and economically. To see the extent of change and progress represented by the second edition, one may turn to the important genus *Cola*, entirely rewritten with the help of Mr. J. P. M. Brenan, and note that twenty-five species have expanded to forty-two and that nine more are recorded as still imperfectly known.

The part now under review is of great economic importance, containing the Leguminosae (divided into Caesalpiniaceae, Mimosaceae and Papilionaceae) and the Meliaceae (African mahoganies). In reviewing a second edition it is hard to decide exactly what criticism is legitimate, in view of the fact that the format of the original cannot be drastically changed. Though Keay has partially removed them, there still remain traces of a certain Kew insularity. It is, one supposes, to be taken as almost axiomatic that any specimen cited is represented in the Kew Herbarium; but this is not always so, and it may be suggested that the internationally accepted system of herbarium abbreviations should have been used to indicate the location of specimens. Of minor errors there are, of course, a few, inevitably so in a work on this scale, but the general standard is very high and to pick out the odd slip for criticism would reflect more on the mentality of the reviewer than on the ability of the editor. The price (55*s.* for 532 pages) is a considerable increase on that of Part 1 (25*s.* for 295 pages) and a stronger paper cover might have been provided in view of the increased bulk. A. W. EXELL

Axial Positive Ion Velocities in Sceptre III

By T. P. HUGHES and DR. S. KAUFMAN

THE spectral lines of highly ionized atoms in the high-current discharges in Zeta and Sceptre[1] show marked Doppler broadening. It has yet to be shown conclusively that the ion motion involved is due to a high ion temperature. If this is the case, one of the conditions which should be satisfied is that the broadening should be independent of the direction from which the discharge is viewed. In the work referred to above, the discharge was viewed only in the radial direction, that is, perpendicularly to the gas current. One aim of the experiments reported here was to make observations of the broadening in the directions parallel to, as well as perpendicular to, the gas current.

The other aim was to measure ion drift velocities. It has been shown[2,3] that those deuterons which undergo nuclear reactions have a mean centre-of-mass velocity parallel to the gas current of about 5×10^7 cm. sec.$^{-1}$. One interpretation of these observations is that a small fraction of the deuterons are accelerated to velocities of about 10^8 cm. sec.$^{-1}$, and that these react with other comparatively slow deuterons[2]. Another possible interpretation is that the gas is moving parallel to the current with a velocity of 5×10^7 cm. sec.$^{-1}$. If impurity ions such as O V were to possess a comparable drift velocity, a marked wave-length displacement would be detected by tangential spectroscopic observations. This point has also been made very recently by George[4]. In this work, preliminary observations have shown that the magnitude of the O V Doppler widths is independent of the line of sight and that some impurity ions (for example, O V, C V) possess axial velocities of about $(1 - 2) \times 10^6$ cm. sec.$^{-1}$ in the direction of positive ion current.

The optical arrangement is shown in Fig. 1. Light leaving the centre of the discharge tangentially was directed into a Hilger medium quartz spectrograph either by the mirrors, *A*, *B* and *C* or by *A′*, *B′* and *C′*, thus allowing observations in opposite tangential directions to be made. The mirror *C* could be replaced by the mirror *C′*, or removed completely to permit radial observations. Spectra from these three lines of sight were recorded for comparison using a Hartmann diaphragm placed in front of the spectrograph slit. Only short exposures of about 50–100 discharges were possible because the quartz window in the torus wall soon became covered with an opaque metallic deposit. The customary few hundred discharges needed to reach stable operating conditions after opening the vacuum system to the atmosphere were therefore omit-

ted, with the result that the impurity concentration was abnormally high.

The spectrograms showed that measurable displacements occurred in the wave-lengths of the O V triplet at λ2781 A., and, in the one set of exposures where it could be seen, of the C V triplet at λ2271 A. These lines are most strongly excited in the central region of the discharge column[5]. The displacements of the O V lines when the direction of the electric field is normal may be seen in Fig. 2, which is an enlargement of a typical spectrogram. Many other lines showed smaller displacements. However, the wave-lengths of several lines of singly ionized metal atoms did not vary perceptibly from one direction of view to another: these lines are but feebly excited at the axis of the torus. One of them, the Mg II line λ2795·53 A., was therefore used as a reference wave-length from which the position of each member of the O V triplet, when viewed in the three different directions, could be obtained by microphotometry: another, the Cu II line λ2276·25 A., served as a reference wave-length for the C V triplet. The results are shown in Table 1. The wave-length displacements are given with respect to the wave-lengths obtained from the radial observations, the latter being in good agreement with published values. Δλ is the mean displacement of the triplet when the discharge is viewed using the mirror system *ABC*, and Δλ′ is the corresponding value when viewing with *A′B′C′*. The mean velocities of the emitting ions have been obtained from these displacements on the supposition that they are due to the Doppler effect alone. The Zeeman effect, which would produce symmetrical splitting of the lines, must be discounted. Only the quadratic Stark effect need be considered. This cannot account for more than a small fraction of the observed displacements because it would produce a shift in one direction only, irrespective of the line of sight. The ion velocities are in each case in the direction of positive ion current flow.

On the basis that the intensity ratio of the two strongest lines of the O V triplet is independent of the direction of view and has a value of 2·0 (measured in previous radial observations when an intensity calibration of the photographic plate was possible) the half-intensity width of the strongest O V line was measured. In Table 1, ΔW_R is the width observed in the radial direction of viewing; ΔW and $\Delta W'$ were obtained for the two tangential directions using mirror systems *ABC* and *A′B′C′* respectively. The mean O V ion 'temperature' was obtained from the average of these widths over all three directions, by the method of Voigt profiles.

The agreement between the Doppler widths for different viewing directions is consistent with the broadening being caused by real O V ion temperatures of about 10^6 deg. K. occurring in the plasma under the operating conditions described above. The existence of such temperatures is not proved conclusively because light from many discharges is required for a single measurement and the possibility of random mass motion still remains. The directed velocities of the O V ions are more than an order of magnitude less than the centre-of-mass velocity of the reacting deuterons. Nevertheless, they are unusually large for positive ions, and their implications are considered by Ware in the following communication. In future work it is hoped to measure these velocities more exactly with a spectrograph of larger dispersion and to ascertain their dependence on ion mass and charge.

We are indebted to Dr. A. A. Ware for helpful suggestions during the preparation of the manuscript and for his constant interest in the work. It is a pleasure to acknowledge the co-operation of Mr. R. F. Hemmings and Mr. J. E. Read, who were responsible for the engineering and operation of Sceptre.

This work was supported in part by a contract from the Atomic Energy Research Establishment, Harwell, and is published with the permission of Dr. T. E. Allibone, director of the Research Laboratory, Associated Electrical Industries, Limited.

The Positive Ion Heating Mechanism in Sceptre III

By DR. A. A. WARE

IN the many experiments which have been made on the pinch effect in both straight and toroidal discharge tubes, the results indicate consistently an electron temperature (T_e) well below that predicted theoretically assuming no heat losses. The electron temperature has been deduced from the electrical conductivity[1,2], spectroscopic data[3,4] and microwave measurements[4], and the results all lie in the range 5 × 10^4 to 5 × 10^5 deg. K. With no heat losses the energy dissipated in the gas would have yielded temperatures 10–100 times greater (see, for example, Allen *et al.*[5]). Similar low electron temperatures are observed in the Stellarator[6]. Several speculations have been made concerning the mechanism by which the electrons lose their energy[6–8], and an important piece of evidence was obtained by Colgate[2], which indicated that a large flux of electrons with energies in the range 2–4 keV. was striking the walls. This

flux was estimated to be of the right order of magnitude to explain the energy loss.

The results of measurements of Doppler broadening of spectral lines from Zeta[9], Sceptre III[5] and the Stellarator[10] are consistent with the positive ions having temperatures appreciably greater than the electron temperature and in the range 10^6 to 5×10^6 deg. K. Because of the possibility of a mass motion occurring in the gas with random magnitude and direction, the results do not prove the existence of these temperatures. If the temperatures are real, the result $T_{\text{ion}} > T_e$ is novel for discharges of this type. Thus, one of the main processes by which the ions were expected to be heated was by collision with electrons[10], but if the ion temperature is greater than the electron temperature, this process becomes a cooling mechanism. Furthermore, the compression of the gas due to the pinch effect is not sufficient to cause the observed ion temperatures, and hence another heating mechanism must be sought.

In the preceding article, Hughes and Kaufman report that the O V and C V ions in Sceptre III have unusually large mean velocities parallel to the gas current. This result suggests a simple picture of the discharge, which is consistent with the high electron energy loss and explains the positive ion heating mechanism.

The Deuteron Velocity

A simple discharge model is taken in which the particle densities and temperatures, and the current density, are assumed uniform over the cross-section of a stationary and stable discharge. (The constant current density is indicated by magnetic probe measurements[11]. The assumption of constant particle density and temperature is not likely to introduce major errors in the following order of magnitude calculations. The assumption of complete stability is least justified because high-frequency oscillations are observed on the magnetic probe signals, and something must be causing the high electron energy losses.) The discharge is assumed to be in equilibrium in the radial direction, and the only motions considered, other than thermal motion, are in the direction of the main gas current. If v_e, v_d and v_0 are the mean velocities of the electrons, deuterons and O V ions respectively in this direction, and if a steady state is assumed, the following mobility equations hold for the O V ions and deuterons respectively:

$$4Ee + f_{e0}\, m(v_e - v_0) + f_{d0}\, M_d(v_d - v_0) + \sum_i f_{i0}\, M_i(v_i - v_0) = 0 \quad (1)$$

$$Ee + f_{ed}\, m(v_e - v_d) + \sum_i f_{id}\, M_i(v_i - v_d) = 0 \quad (2)$$

E is the component of the electric field in the direction of the gas current, m and M_d are the masses of the electron and deuteron, and f_{xy} is the collision frequency for momentum transfer for ions of type x colliding with a single ion of type y. The symbol i refers to an impurity ion, and the summation must be made over all types of impurity ion present, but with the omission of O V ions in equation (1). The loss of momentum by the particles to the walls has been neglected (see below). The gas current is given by:

$$I = N_d e\,(v_d - v_e) + \sum_i N_i Z_i\, e\,(v_i - v_e) \quad (3)$$

where N_i is the number of ions of type i per unit length of the discharge and $Z_i e$ the charge on such an ion.

That the terms due to impurities are of significance in equations (1)–(3) is suggested by the intensity of impurity spectral lines and also by the fact that without impurity terms, equations (2) and (3) yield a value for T_e (from f_{ed}) of 9×10^4 deg. K., whereas the measured temperature was $2\cdot5 \times 10^5$ deg. K.[3]. (T_e was obtained from the relation $f_{ed} = n_d e^2 \eta_\perp / m$, where the resistivity $\eta_\perp$ is given by Spitzer[12a].) The presence of the impurity terms makes it impossible to solve the equations because the densities and velocities of the various impurities are unknown. It is possible, however, to form general conclusions concerning the velocity v_d.

In order to do this, the impurity terms containing i are at first neglected in the three equations. Using the experimental results for two of the cases reported by Hughes and Kaufman (preceding communication), the values of f_{ed} have been calculated from equations (2) and (3) and then v_d and v_e from (1) and (3). The value of f_{e0} was obtained from the relation:

$$\frac{f_{e0}}{f_{ed}} = \frac{Z_0^2}{Z_d^2} = 16 \quad (4)$$

The quantity f_{d0} was calculated using the expression given by Spitzer[12b], with T_d assumed equal to T_0 (see below) and taking $n_d = N_d/\pi a^2$, where a is the observed radius of the discharge from magnetic probe measurements (Table 1) and N_d the number of deuterium atoms present initially in the discharge per unit length.

The results in Table 1 give values of v_d greater than v_0 and approximately equal to $-v_e$. That v_d should, in general, be greater than v_0 can be seen from the fact that f_{e0} is 16 times greater than f_{ed}, whereas the electric force on the O V particles is only four times greater. Hence the electric field should cause the deuterons to have a larger drift velocity with respect to the electrons than the drift velocity of the O V particles, so that $v_d > v_0$. The deuteron – O V collision term acts merely to reduce the magnitude of the difference between v_d and v_0.

Considering now the effect of the impurity terms, in general the ratio f_{i0}/f_{id} will not be 16, because the average relative velocities between colliding particles will not be the same for the two types of collisions as was the case in equation (4). However, provided that:

$$\frac{T_d}{T_0} > \left(\frac{16\ M_d}{Z_0^4 M_0}\right)^{1/3} \simeq 0\cdot 2$$

f_{i0}/f_{id} will always exceed 4, and the electric field will cause the deuterons to have a larger drift velocity with respect to the i-particles than that of the O V ions and again $v_d > v_0$. The inclusion of the impurity terms in equations (1) to (3) plus the fact that a higher electron temperature must be taken to satisfy equation (2) leads to values for v_d closer to v_0 than those in Table 1. Thus for the given experimental conditions the theoretical model predicts that v_d lies in the range $v_0 < v_d < (v_d - v_e)/2$.

Using the velocities from Table 1, the net momentum of the gas per unit length of the discharge is approximately NM_dv_d, neglecting the contribution due to impurity ions. This is of the order of 1 dyne sec. cm.$^{-1}$. The momentum received by the electrons per unit length of the discharge during the time to reach peak current ($t \simeq 300$ μsec.) is of the order $-2N_dEet/\pi$, which is about -50 dyne sec. cm.$^{-1}$. Hence the large ion velocities are explained if the electrons lose to the walls about 2 per cent of the momentum that they gain from the electric field. The simplest explanation of this momentum loss is that there is an appreciable electron particle loss to the walls. As already mentioned above, Colgate has obtained evidence for such a loss in his experiment. In the case of Sceptre III, if it is assumed that the momentum loss is carried by electrons in this way, the losses of momentum and energy can be reconciled, provided the mean energy of the electrons reaching the wall is less than 2 keV.

The Positive Ion Heating Mechanism

A significant feature of the above estimates of v_d is that the positive ions are carrying an abnormally high fraction of the gas current; the fraction is somewhere in the range 6–50 per cent. (If there were no losses from the discharge, the electrons and deuterons would have equal and opposite momenta, and the deuterons would carry only 0·03 per cent of the current.) Thus, the positive ions will receive a substantial fraction of the energy input directly from the electric field. The energy is converted to thermal energy as a result of particle collisions, and if collisions with electrons are the main resistance to the positive drift velocity then most of the energy will be transferred to thermal energy of the electrons because of the low electron mass. If, however, the dominant collisions are those with impurity ions, that is, if the sum of the terms containing f_{id} in equation (2) exceeds the term containing f_{ed}, the deuterons will retain most of the energy, since the impurity ions have masses large compared with the deuteron mass.

Assuming the latter to be the case and neglecting cooling processes for the deuterons other than by collisions with electrons, the deuterium temperature is given by:

$$Eev_d = \frac{3}{2}k\left(\frac{T_d - T_e}{t_{ed}}\right) \qquad (5)$$

where t_{ed} is the relaxation time for energy exchange and is given by Spitzer[12c]. Using the two limits obtained above for v_d, the deuterium temperature should lie in the range 8×10^5 to $1\cdot 7 \times 10^6$ deg. K. for the 500 gauss case and 6×10^5 to $2\cdot 8 \times 10^6$ deg. K. for 1,000 gauss. In the case of the O V ions, in order that these ions should retain most of the energy they receive from the electric field, the impurity ions must be the main resistance to the O V motion and most of the ions must have masses greater than that of oxygen. (Copper and aluminium have strong lines in the spectra.) In such a case the equation for the O V particles corresponding to equation (5) predicts values of T_0 of $1\cdot 3 \times 10^6$ and $1\cdot 0 \times 10^6$ deg. K. for 500 and 1,000 gauss respectively. In any event, at the temperatures involved here the rate of exchange of energy between deuterons and O V ions is about twice as rapid per unit temperature difference as that between O V and electrons. Hence, in general T_0 would be nearer to T_d than to T_e. Thus the theory predicts positive ion temperatures close to those indicated by the Doppler broadening (T. P. Hughes and S. Kaufman, preceding communication).

Conclusions

A simple model has been taken for the discharge in Sceptre III, and on this basis it has been deduced that the deuterons should have a mean velocity somewhat greater than that observed for the O V ions. The appreciable gas momentum involved is consistent with the electrons losing to the walls a small percentage of the momentum they receive from the electric field.

The discrepancy between the electron temperature calculated from the resistivity of the gas and that measured spectroscopically suggests that impurity ions may play a major part in scattering the deuterons. If this is so, the deuterons will retain most of the energy they receive from the electric field, and positive ion temperatures of the order of magnitude indicated by Doppler broadening for O V are to be expected. The theory thus shows that there is a simple and consistent explanation of the Doppler broadening on the basis that thermal motion is the cause. Because of the simplifying assumptions which have been made, however, the theory cannot be regarded as a proof of the existence of such temperatures.

I wish to acknowledge many helpful discussions with Mr. B. S. Liley and other colleagues at the Associated Electrical Industries Research Laboratory and with members of the Thermonuclear Division at the Atomic Energy Research Establishment, Harwell. The work reported here has been done under contract to the Atomic Energy Research Establishment, and I am grateful to Dr. T. E. Allibone, director of the Research Laboratory, Associated Electrical Industries, Ltd., for his continued encouragement and permission to publish this communication.

ELECTRONIC COMPUTERS IN THE SERVICE OF BUSINESS

At a distance of some days, it is possible to unscramble the many and varied impressions created at the Electronic Computer Exhibition and Business Computer Symposium (Olympia, London, November 28–December 4), and to consider what one feels are the more important implications. One may put aside such technical developments as the increasing use of printed circuits in place of wiring and of transistors in place of thermionic valves: such matters are applicable to the electronics industry as a whole. One may also disregard a number of technically interesting but somewhat irrelevant demonstrations, and the bread-and-butter exhibits of stationery, furniture and office equipment. It then becomes apparent that the most prominent feature of the Exhibition and Symposium was the emergence, in parallel, of a classic approach to the introduction of integrated electronic data-processing for business purposes, and of a fashion in the design of computer systems directed to cater for this approach.

That business has now taken over from scientific research the role of principal instigator of the development of computers can be clearly inferred not only from the types of computer system on show, but also and more directly from the fact that the majority of displays were of computer systems rather than of simple computers. The predominant trend in design is towards what Lord Halsbury in his opening address to the Symposium described as the "fully literate computer": one which is designed to read information from the widest possible range of input media (manual keyboard, punched paper tape, punched cards and magnetic tape), and can write information on an equivalent range of output equipment; one which, moreover, can grant a considerable measure of autonomous control to its input and output facilities so that these may proceed independently, transferring information to or from buffer storage in readiness for the central computer's demands. Such a trend must be to the gratification of one manufacturing organization, at least, which was operating electronic data-processing equipment on something approaching this basis at a time, four years ago, when no other general business electronic data-processing installation existed.

In an attempt tp keep up with this trend, some small and medium-sized computers have followed the tactics of the puffer fish. Though thoroughly competent in the role for which they were originally designed, these machines are being required to support a burden of peripheral equipment out of all proportion to their normal capacity. Prospective purchasers may well consider whether there can be any justification for tying upwards of £100,000 worth of input, output and ancillary storage equipment to the apron strings of a computer which is incapable of utilizing effectively more than a small proportion of its potential activity. It was equally regrettable to note the manner in which one or two exhibitors sought to attract attention by stunts which had little or no connexion with the intended application of their equipment. "Good wine needs no bush", and an effective computer does not require a 'gimmick'.

In respect of ancillary equipment, one could discern another important trend. While mechanical equipment is being pushed to the utmost to achieve greater speeds of printing, punching and hole sensing, in one corner of the exhibition could be seen the all-electronic writing on the wall. A prototype printing device was on show in which the characters, delineated by deflexions of the beam of a cathode-ray tube in response to signals decoded from a magnetic tape, are used, by means of a system of optical projection and static charges, to deposit powder in appropriate shapes upon a continuously moving roll of paper. The powder is then bonded to the paper by heat treatment, emerging as a succession of lines of print to be taken upon an output roller. The speed of output by this equipment is of the order of ten times that of the most rapid mechanical line printer on show, yet the only moving parts are the slowly revolving rollers. Elsewhere could be seen prototype equipment which, by use of cathode-ray tube scanning and photo-multipliers, could, in a continuous process, read typescript characters from a document and code these in computer language on to magnetic tape. Such equipment, when perfected, will have two great advantages. High-speed mechanical equipment, particularly when reciprocating motion is involved, is not infrequently subject to mechanical breakdown. In order to avoid interrupting the flow of work while spare parts are obtained and repairs are made, it has become common practice to install an expensive spare machine which will be idle for a considerable part of the time. Moreover, the direct automatic conversion from original document to computer language and from the latter to printed output will eliminate the intermediate steps in which human errors are likely to be introduced.

The classic approach to an integrated electronic data-processing system was apparent in a well-developed form in three of the papers presented at the Symposium, and in an embryonic state in at least three more. It reflects the growing confidence of business management in the feasibility of such a system, as exemplified by the comment of one speaker that if his system of completely integrated data-processing did not prove satisfactory he would be obliged to seek a new occupation. This attitude is a far cry from the somewhat timid and tentative approaches to electronic data processing of some applications represented at the Symposium but not representative of it. The classic approach involves a penetrating research into the very fundamentals of the existing business system, questioning why the various functions are performed, rather than investigating the exact manner of their performance. It is essential, of course, that such an investigation should be carried out under the close direction of persons of managerial or senior supervisory calibre. Many speakers at the Symposium were agreed that it was equally necessary that the 'organization and methods' personnel concerned in investigations for an electronic data-processing system should have a sound general knowledge of programming techniques and that programmers should be acquainted with 'organization and methods' procedure. The two can then work in close collaboration to determine the nature of the original information available for input and that of the various types of output information which should be proved necessary or desirable. From this they would devise an efficient system for achieving the requirements, using the full range of equipment available. Carried to its logical conclusion, such an investigation should not consider the somewhat arbitrary divisions into which a business may be divided at present (for example, wages and salaries, cost accountancy, production and stock control, sales invoicing), but should include the whole scope of the business. This may sound a Utopian concept, but it is already being attempted by some, and is considered the essential goal by many others.

The essential element of such an approach is the open mind, uninhibited by existing manual or punched-card clerical systems. Some business organizations which have not yet installed mechanized systems of any kind have considered adopting a little-by-little approach; a gradual transition by introducing first a punched-card system, then a small-scale computer, and finally a fully developed large-scale computer system. To these the experience of one business organization may be of interest and provide some guidance. The spokesman of this concern explained that the computer system now being installed bears very little resemblance to the punched-card system which preceded it, although he acknowledged that the latter had provided some useful experience in planning.

It is true that the applications of a limited scope may sometimes be of outstanding importance. A saving of the order of £50,000 per annum for the expenditure of three or four hundred pounds was reported at the Symposium from the application of linear programming techniques to a problem of bulk transportation, and an account was given of how an hour or so a week on a small computer had made possible the introduction of a greatly improved method of production control. But in general, the most substantial benefits will come from a comprehensive system. This does not imply that an integrated system can be installed in one operation. The system must be planned with the view of dividing it into phases which are of such a size and nature that they may be introduced in sequence over a period of many months. The transition, indeed, requires some of the most careful and detailed planning, for each phase must be introduced with the least possible disturbance both to work already on the computer and to procedures which are still carried out manually. It is normally advisable to run each new phase on the computer in parallel with the previous system until it is reasonably certain that all eventualities have been covered. Furthermore, it is prudent to prepare in advance an emergency procedure for adoption in the event of a serious breakdown of the equipment, however unlikely this may be.

Compared with strategical planning of such complexity, the tactical programming may well prove relatively simple. However, just as interpretive routines and automatic coding techniques permit the computer to assist the programmer, so may some of the computer techniques which are being developed in the field of operational research be of assistance to the planner. A paper on developments in this field was presented at the Symposium, and the speaker agreed with a suggestion that the simulation techniques which he had described could be used to study the feasibility of systems designed for a business electronic data-processing installation. A large organization might find it worth while to acquire a small computer initially for this purpose. If this machine were compatible with the peripheral equipment of the proposed large installation, it could later be used in conjunction with it, and would prove invaluable for carrying out those housekeeping activities such as sorting and merging which occupy so much of the time of a large computer while exploiting so little of its capabilities. This, then, may represent the pattern for the future use of electronic computers in business.

In conclusion, I wish to make it plain that the opinions expressed above are of a purely personal nature, and should not be construed as representing the policy of the organization with which I am associated.

W. L. C. Garrett

SCIENTIFIC CENTENARIES OF 1959

By JOAN M. EYLES

ONE of the first requisites for the traveller is a good map of the country in which he proposes to travel. If none exists, then his travels will help to provide one. The launching of the First Crusade in 1095 by Pope Urban II marked the beginning of a series of mass pilgrimages across Europe which continued for nearly two centuries and must have given rise to a demand for maps, guides and charts to help the traveller on his way. The earliest medieval maps of Britain are those made by Matthew Paris, the great historian. Matthew, a Benedictine monk of the Abbey of St. Albans, died seven hundred years ago, in 1259, and his maps of Britain are believed to date from 1250. Their main object was probably to show the towns and monastic guest-houses where the pilgrim could rest on his way to Dover, the usual point of departure for the Holy Land. Many of the legends on the maps are of interest; Snowdon is both named and shown by an outline of a mountain, a convention that survived on maps until the middle of the eighteenth century, when hachuring came into use. Other maps prepared by Matthew Paris which still exist include one showing the route from London to southern Italy.

When William Harvey described the circulation of the blood in his "De Motu Cordis" (1628), he referred to the Italian anatomist, Matteo Realdo Colombo, who died in 1559, and whose work, "De Re Anatomica", appeared shortly after his death. Colombo, a pupil of Vesalius, made a close study of the blood vessels of the lungs and discovered experimentally the pulmonary circulation, although he did not understand or recognize the general circulation. Colombo was appointed successor to Vesalius at Padua in 1545, but went to Pisa in the following year and taught there. Later he moved to Rome, where he was teaching when he died.

Two authors of arithmetic books died in 1559. One was Cuthbert Tunstall, Bishop of London and friend of Sir Thomas More, whose "De Arte Supputandi", written in Latin and first printed in 1522, was the earliest arithmetic by an English author. The other was Adam Riese, born in Bavaria in 1489, who wrote a popular arithmetic and a treatise on practical geometry. His arithmetic was so widely used that "Nach Adam Riese" can be looked on as equivalent to the English expression "according to Cocker".

Among the bicentenaries of the year, that of the French scientist, P. L. M. de Maupertuis, who died on July 27, 1759, is particularly interesting. De Maupertuis was leader of the French expedition to Lapland in 1736 to measure the length of a degree of longitude, achieving results which verified Newton's theory that the Earth was an oblate spheroid. He became president of the Royal Academy of Sciences in Berlin, and was afterwards involved in a bitter controversy with Voltaire. It is worth recording that he also had ideas about evolution and made an early attempt to explain the origin of new species.

Jacob T. Klein, born in Königsberg in 1685, and author of several zoological works, also died in 1759. Klein visited England in the course of his travels, and in 1728 was elected a Fellow of the Royal Society.

A significant event of 1759 was the establishment of a botanic garden in the grounds of Kew House, on the instructions of Augusta, Dowager Princess of Wales and mother of George III. Some thirty years later, Erasmus Darwin wrote:

> "So sits enthron'd in vegetable pride
> Imperial Kew by Thames's glittering side;
> Obedient sails from realms unfurrow'd bring
> For her the unnam'd progeny of spring;"

From these beginnings arose the magnificent Royal Botanic Gardens at Kew which we know to-day.

Several well-known naturalists were born in 1759. In particular, we note Sir James Edward Smith (1759–1828), founder and president for forty years of the Linnean Society of London. The story of how the young botanist was breakfasting with Sir Joseph Banks and seized the opportunity of purchasing the collections of Linnæus has often been related. This memorable purchase was followed by several years travel in Europe, and on his return Smith founded the Linnean Society. This was not the first Society started by Smith, for some years before, when a student at Edinburgh, he and a few friends with similar interests had formed a Society for the pursuit of natural history, which was attended by men as prominent as Black the chemist and Hope the botanist.

Born on August 12, 1759, a few months before Smith, Thomas Andrew Knight, a country gentleman, also became known as a botanist and founder of a Society. Knight was another member of the Banks circle, and one of Sir Joseph's many correspondents. He became a Fellow of the Royal Society in 1805 and in the following year received the Copley Medal for his investigation of tropisms in plants. He also carried out extensive researches into the improvement of fruit trees by crossing. One of the founders of the Horticultural Society, he became its second president in 1810, a position he occupied until his death in 1838.

Another enthusiastic naturalist was the Rev. William Kirby, rector of Barham in Suffolk, whose name appears on the first list of Fellows of the Linnean Society. Kirby's chief interest was in entomology, and he is remembered as joint author with Spence of a popular introduction to entomology.

Three French naturalists born in 1759 were L. A. G. Bosc, who travelled extensively in North America, J. B. Audebert, artist and author of several beautifully illustrated books, including "L'Histoire Naturelle des Singes", and P. J. Redouté, the famous flower painter.

An interesting chemical anniversary is that of the birth of Thomas Cooper, free-thinker and student of the natural sciences, who emigrated to America in 1793. He was a close friend of Priestley, who bequeathed to him his chemical apparatus, including the historic burning glass used in the discovery of oxygen. Cooper taught chemistry and mineralogy in the United States for many years, first in Pennsylvania, then in Virginia, and later in South Carolina. His advanced thinking and love of free speech, which had led to his leaving England, brought him into further trouble in America, and in 1833, after writing to Silliman that "the Old as well as the New Testaments were by no means infallible guides in mineralogy and geology", he was forced to resign his position as president of the College of South Carolina. Cooper did much to spread the knowledge of the new chemistry of Lavoisier in the United States, and edited a number of chemistry text-books; but he was an unorthodox character, whom an English geologist described as "a most remarkable man some of whose screws were uncommonly loose".

The first practical demonstration of aerostation in England was made by Vincenzo Lunardi (1759–1806), a daring young Italian diplomat, who ascended in a balloon from Moorfields, London, on September 15, 1784. He travelled some twenty-four miles in two and a quarter hours, touching down at North Mimms on the way to land his cat, which was suffering from the cold. This aerial voyage was watched by thousands of people, including the Prince of Wales and prominent politicians.

Passing to 1859, undoubtedly the most eminent of the scientists who died in that year was Alexander, Baron von Humboldt. Born in Berlin in 1769, he studied first at Göttingen and later at the School of Mines at Freiberg. On leaving the latter he received an appointment in Berlin as superintendent of mines. For four years he carried out his duties, visiting mines and studying geology. In 1796 he gave up his post and devoted himself to further scientific studies in order to prepare himself for travel. After several disappointments, in 1799 he set sail for South America with the botanist Aimé Bonpland, having obtained special permission from the King of Spain to travel in and examine Spanish territories in the New World. It was five years before he returned to Europe, having travelled some 40,000 miles, bringing back with him more than thirty cases of geological and botanical specimens. During 1808–27 he made his home in Paris, which he regarded as the centre of the scientific world, and devoted himself to preparing detailed accounts of his travels and the collections he had made. In 1827 he moved to Berlin, and he remained in Germany until his death in 1859. He had hoped to travel in Asia as extensively as he had in America, but the realization of his hopes was limited to a nine-months journey across Russia and Siberia in 1829.

Humboldt made many contributions to science, in the fields of geology, geography and climatology, but he is also remembered for the inspiration he was to others, and in particular to Charles Darwin. The latter wrote in 1845: "I never forget that my whole course of life is due to having read and re-read as a youth his 'Personal Narrative'". A. R. Wallace, too, wrote of the influence this book had upon him. When Humboldt died, on May 6, 1859, he was within six months of his ninetieth birthday, and ten years later the centenary of his birth was celebrated with enthusiasm on both sides of the Atlantic.

Karl Ritter, the geographer, who also derived inspiration from Humboldt's writings, died only a few months later, in September 1859. Ritter did much to establish the science of comparative geography, and endeavoured to show that the physiography of a country had a direct influence on the life and progress of the nation inhabiting it.

Another scientific traveller who spent many years in the United States was Thomas Nuttall (1786–1859), a Yorkshire printer who emigrated in 1807. He was persuaded to take up botanical studies, and underwent many hardships during his solitary travels in the interior of the United States in search of specimens. He is said to have discovered an almost unequalled number of new genera and species. During 1825–34 he was curator of the botanic gardens at Harvard, but in 1841 returned to England to occupy a family estate at Nutgrove, near Liverpool, where he cultivated many rare plants. He died on September 10, 1859, and his herbarium of more than 5,000 species was purchased by the British Museum.

The British Museum also acquired the herbarium of Javanese plants belonging to Thomas Horsfield (1773–1859), a Pennsylvanian-born physician who practised in Java and Sumatra from 1799 until 1819, when he became keeper of the East India Company's Museum in London. Yet another botanist who died in 1859 was K. A. Agardh, born in Sweden, who published the first general account of diatoms. His "Systema Algarum" (1824) entitles him to be regarded as a pioneer in the classification of the algae.

In the field of geology, Denison Olmsted (1791–1859), a Yale graduate who became professor of chemistry, mineralogy and geology at the University of North Carolina, was one of the first to appreciate the value of a State geological survey. He laid a plan for one before the State legislature in 1821, and an Act authorizing such a survey was passed two years later. Olmsted received no fees, but expenses of 250 dollars a year. His preliminary reports were published in 1824 and 1825. He was then recalled to Yale as professor of mathematics and natural philosophy. Later he became professor of astronomy at Yale, and observed the return of Halley's comet in 1835, making the announcement long before confirmation arrived from Europe.

Four years after this event, Harvard decided to establish an observatory, and William Cranch Bond (1789–1859) was appointed 'observer', later becoming its first director. Bond was an instrument-maker in Boston with a taste for astronomy, who had constructed his own instruments and built an observatory at his home. When he died in 1859, he was succeeded at Harvard by his son, George Phillips Bond.

Three mathematicians of some note also died in 1859. The most senior, Louis Poinsot, was born in Paris in 1777. He was particularly interested in statics, but published a number of works on geometrical and mechanical subjects. The theory of couples is largely due to him, also that of the motion of a body in space under the action of no forces. J. L. Raabe, of Zurich, born in 1801, chose higher algebra for his field of research, and discussed the convergency of series; while Peter Lejeune Dirichlet, born at Duren in 1805, became a pupil of Gauss, and succeeded him at Göttingen in 1855. He is best known as an interpreter of Gauss and of Jacobi, his father-in-law, but is also remembered for having introduced into the calculus of variations the so-called Dirichlet principle.

The tubular girder railway bridge spanning the Menai Strait in North Wales and the High Level bridge across the Tyne at Newcastle both stand as memorials to the famous engineer, Robert Stephenson, son of an equally famous father. Stephenson died in October 1859, and was buried in Westminster Abbey.

Passing on to more recent times, and the centenaries of scientists who were born in 1859, we note first two who were awarded Nobel Prizes, Pierre Curie and Svante Arrhenius. Pierre Curie, born in Paris on May 15, 1859, married the young Polish chemist, Marja Sklodowska, in 1895. Six months later Röntgen discovered X-rays, and so began that well-known chapter of scientific history in which is recorded the Curies' joint investigation of the radioactive elements. Pierre had already studied the behaviour of crystals in electromagnetic fields, and had discovered the piezo-electric effect. To the joint research he brought a familiarity with delicate electrical instruments which proved of great value in determining the physical properties of the newly discovered elements. In 1903, the announcement by Pierre Curie and his pupil, Laborde, that radium emits heat rendered valueless Kelvin's estimate of the age of the Earth, based on its rate of cooling, and paved the way for an entirely new method of estimation, based on radioactivity.

In the same year, the Curies and H. Becquerel shared the Nobel Prize for Physics. Three years later, a street accident brought a tragic end to Pierre's life, though, as all know, the work on radioactivity was carried on valiantly by his widow, who herself received the Nobel Prize for Chemistry in 1911.

While Pierre Curie was studying the passage of electricity through crystals, Svante August Arrhenius, born near Uppsala on February 19, 1859, was investigating its passage through dilute solutions. His theory of electrolytic dissociation, first embodied in the dissertation for his doctorate in 1883 and published in full in 1887, received more support abroad, particularly from Ostwald and Van 't Hoff, than in Sweden. Recognition eventually came, and with it the Nobel Prize for Chemistry in 1903, and the establishment in 1909 of a Nobel Institute in Stockholm, which he directed until his death in 1927. His bold and original ideas were not confined to physical chemistry, but extended to the fields of serum therapy and cosmology, volcanism and the cause of glacial periods. Appreciation of his work was shown in British scientific circles by the conferment of foreign membership of the Royal Society and of honorary degrees by the Universities of Oxford, Cambridge, Edinburgh and Birmingham.

Two men born in 1859 both occupied prominent positions at the Rockefeller Institute for Medical Research in New York. One was Jacques Loeb, biologist and biochemist, born at Mayen in Germany, who left his homeland for the United States in 1891. He spent ten years in Chicago, seventeen at Berkeley, and was then made head of the Division of General

Physiology in the Rockefeller Institute, a position which he held until his death in 1924. Founder of the modern school of physiology, his early experiments in artificial parthenogenesis startled the scientific world by producing the fatherless sea-urchin and the fatherless frog. He investigated the effects of various stimuli upon living matter, and followed this by extensive research on proteins. Although a brilliant experimentalist, his philosophical ideas, particularly as stated in his "Mechanistic Conception of Life", aroused considerable criticism and opposition.

Loeb's contemporary, Theobald Smith (1859–1934), of Albany, New York, occupies an honoured place in medical science for his pioneer work investigating the transmission of disease and immunization. Inspired by the work of Koch, in 1889 he discovered the parasite responsible for Texas fever in cattle, and in his classic report of 1893 gave the first account of the transmission of a parasitic protozoan by a blood-sucking parasite. Later, he clearly differentiated between the bovine and human types of tubercle bacilli. He was the first occupant of the chair of comparative pathology at Harvard, and was eventually appointed director of the Department of Animal Pathology in the Rockefeller Institute. He was elected a foreign member of the Royal Society in 1932.

Two well-known British geologists were born in 1859, namely, Alfred Harker and G. W. Lamplugh. Harker, while retaining his lectureship at Cambridge, was for ten years attached to the Scottish Geological Survey. This period was devoted to mapping the volcanic rocks of Skye and other islands of the Inner Hebrides, and his descriptions of these rocks became classics in geological literature. His later more general works on igneous rocks and metamorphism also exerted a lasting influence on petrological thought. He died in 1939, six months after the celebration of his eightieth birthday. G. W. Lamplugh had his first geological paper, on glacial drift in Yorkshire, published when he was only nineteen. He joined the Geological Survey in 1892, and during the next five years completed almost single-handed the mapping of the Isle of Man. Afterwards he carried out an extensive examination of the Irish glacial deposits. He retired from the Survey in 1920 and died six years later. Both Harker and Lamplugh were Fellows of the Royal Society and each had occupied the presidential chair of the Geological Society.

A rather controversial figure in the history of science is that of the Russian physicist, A. S. Popov (1859–1905), a pioneer in the field of radio telegraphy, whose success in signalling has been claimed as antedating that of Marconi. Others born in 1859 include the organic chemists, J. B. Cohen and L. Knorr, the American chemist H. Y. Castner, whose name is associated with the Castner–Kellner process for the manufacture of chlorine and the extraction of sodium, and Florian Cajori, historian of mathematics.

NEWS and VIEWS

Contributions to *Nature*

DURING the first year of the publication of *Nature* (November 1869–November 1870), the number of original communications (mainly "Letters to the Editor", together with some special articles, though not the general ones) was 378. These came from 17 different countries. In certain selected years afterwards, the number of original communications were as follows (number of countries in parenthesis): 1910, 285 (19); 1920, 422 (17); 1930, 568 (27); 1937, 648 (31); 1949, 1,066 (35). During last year (1958), the number of such communications was 2,362, and these were submitted from 59 different countries. These were distributed as follows:

Argentina	2	Japan	80
Australia	128	Kenya	13
Austria	2	Malaya	7
Belgian Congo	3	Mauritius	1
Belgium	41	Mexico	1
Brazil	6	New Zealand	53
British Borneo	1	Nigeria	9
British Honduras	1	Norway	14
British West Indies	11	Pakistan	2
Canada	67	Philippines	1

New Science Officers for American Embassies

SEVEN distinguished scientists have been appointed by the U.S. Department of State to serve as science officers in the American Embassies in London, Paris, Rome, Bonn, Stockholm, and Tokyo. Although assigned to a specific embassy, the science officer will also provide scientific assistance in embassies in adjacent areas. The men selected are: Dr. Thomas H. Osgood, dean of the School for Advanced Graduate Studies, Michigan State University, for London; Dr. Edgar L. Piret, professor of chemical engineering, University of Minnesota, for Paris; Dr. Edward H. Cox, retired head of the Department of Chemistry, Swarthmore College, as deputy science officer for Paris: Dr. Walter Ramberg, chief of the Mechanics Division, National Bureau of Standards, for Rome; Prof. Ludwig F. Audrieth, professor of chemistry, University of Illinois, for Bonn; Dr. Julian E. Mack, professor of physics, University of Wisconsin, for Stockholm; and Prof. Willis R. Boss, professor of zoology, Syracuse University, for Tokyo. The appointments, which will be for a period of two years, constitute the first of a series for the Science Programme of the Department of State under Dr. Wallace R. Brode, science adviser to the Secretary. Still to be appointed are science officers for the U.S.S.R., India and South America, and deputy science officers for all the posts with the exception of Paris, to which Dr. Cox is being assigned. Leaders in science who have had experience as educators, research workers and administrators have been especially selected for these posts because of their international scientific reputation, and their knowledge of the status of science and acquaintance with scientists in the country of assignment. Each of those appointed also has a facility with the language of the country of assignment. A science officer's primary role will be to serve as an adviser to the Ambassador and his staff in the evaluation of the interaction of science with foreign policy, the assessment of current scientific progress abroad and the enhancement of the liaison between United States and foreign scientists and engineers.

British Scientific Attachés Overseas

REPLYING to a question in the House of Commons on December 8 regarding scientific attachés, Mr. G. M. Thomas, Parliamentary Secretary to the Ministry of Works, as representing the Lord President of the Council, said that the British Embassies at Washington, Paris, Bonn and Stockholm had a scientific attaché on their staff. The choice was now being made of a suitable person for scientific attaché to the British Embassy in Moscow and the appointment of scientific attachés to certain other embassies was under consideration.

Department of Scientific and Industrial Research : New Five-Year Plan

MR. HARMAR NICHOLLS, Parliamentary Secretary to the Ministry of Works, speaking on behalf of the Lord President of the Council, announced in the House of Commons on December 19 that expenditure on research by the Department of Scientific and Industrial Research will be nearly doubled in the next five years. Under its second five-year plan, for the period 1959–64, approximately £61 million will be made available to the Department, compared with £36 million for the first quinquennium which ends on March 31. By 1963–64 expenditure is planned to reach about £14 million, excluding the British contribution to the European Organization for Nuclear Research (C.E.R.N.) which will continue to be financed outside the five-year plan. The largest expansion will be in university grants. Postgraduate awards will be increased by about 10 per cent each year, until in 1963–64 some 3,800 students will be receiving grants from the Department for research, and support for special research in universities will amount to £1¾ million per annum.

In support of additional research carried out in the Department's own laboratories, expansion of staff at the rate of about 6 per cent per annum is included in the plan. Grants to the research associations financed jointly by the Department and industry will also be increased to more than £2 million per annum by the end of the period. It is also proposed that the Ministry of Works shall increase its rate of expenditure on behalf of the Department so as to provide buildings and equipment for the increased staff of its laboratories. The works programme includes the provision of a new laboratory at Crowthorne, Berkshire, to rehouse the Road Research Laboratory which at present occupies two separate sites a few miles apart, one at Harmondsworth, Middlesex, and the other at Langley, Bucks. The new Road Research Laboratory will include an experimental road system 3½ miles long.

Public Expenditure on Education

IN written answers in the House of Commons on December 17, Mr. Geoffrey Lloyd, Minister of Education, said that expenditure by the Ministry and local education authorities, excluding capital expenditure, was expected to be about £46 million in the current year, rising to about £57 million in 1960–61. To give maximum maintenance grants to 50,000 additional pupils of sixteen and seventeen at the approved rates would cost about £16 million a year. To reduce all classes to a maximum of thirty by about 1965 would cost about a further £200 million a year, with some £140 million on training additional teachers.

Exchange of Personnel between the Post Office and Industry

ON December 17, the Postmaster-General, Mr. H. Marples, in reply to a question in the House of Commons, said that on January 5, a Post Office administrator and a Post Office engineer would take up temporary appointments with Unilever, Ltd., and two Unilever men would go to the Post Office. The exchange was expected to last about a year, and discussions with another concern were in progress. He hoped the experiment would be a forerunner of a regular interchange of experience between the Post Office and industry and contribute mutual benefit and a better understanding of each others' problems.

Pharmacology at the Royal College of Surgeons

THE Royal College of Surgeons of England has received a gift of £150,000 from Mr. G. A. Vandervell for the endowment of its chair of pharmacology. More than ten years have elapsed since those responsible for the rehabilitation of the College after the Second World War recognized that a Department of Pharmacology should be added to the existing departments of anatomy, pathology and physiology, for without it the education of postgraduates in the basic medical sciences would have been incomplete. A still more important objective, however, was the promotion of research into the action of drugs and other substances used not only by surgeons but also by dentists and anæsthetists, who are represented by faculties within the College. The Department was therefore established six years ago, and has flourished under the able direction of Prof. W. D. M. Paton, whose researches into the chemical mediation of nerve impulses are so well known. He and his assistants have been housed temporarily at the Examination Hall, Queen Square, but will shortly be moving into the new buildings in Lincoln's Inn Fields. Since the College is an independent body and therefore does not receive a direct grant from the University Grants Committee or from any other Government source, the Department has been financed hitherto partly by generous contributions from the chemical and pharmaceutical industries. This donation from Mr. Vandervell, which will endow the chair in perpetuity, is doubly welcome since it comes at a time when the College is facing heavy increases in expenditure owing to the extension of its research activities.

National Lending Library for Science and Technology

THE Department of Scientific and Industrial Research will take over part of the former Royal Ordnance Factory at Thorp Arch, near Boston Spa, Yorks, for the use of the new National Lending Library for Science and Technology. Present proposals indicate that the library will begin operating at Thorp Arch in 1961 and become fully operational during the following year. Existing large single-story buildings will be converted into offices and bookstores, and the site provides adequate room for expansion in the future. The new library—the nucleus of which already exists in the Department's Lending Library Unit now at Chester Terrace, Regent's Park, London—will cover all subjects in science and technology, except for some fields of medicine. It will take over the responsibility for the lending service now provided by the Science Museum Library, which in future will concentrate on serving the needs of the enlarged Imperial College of Science and Technology. It is also taking over some of the literature now held by the Science Museum Library. The present Lending Library Unit has been collecting literature for the National Library since 1957. It already operates a loan service for Russian literature which is being progressively extended to cover publications from other countries. Eventually, much of the scientific and technological literature in the world will be included in this collection, to make it the most comprehensive of its kind in the United Kingdom. The new library in Yorkshire will make its unique collection available to research, industrial, educational and other organizations by loans and photographic reproduction. Its primary objective will be to encourage the greater use of scientific and technical literature. One important activity will be the expansion of work on the translation of Russian scientific literature, now organized by the Lending Library Unit in collaboration with the National Science Foundation in the United States. It remains distinct from the National Reference Library of Science and Invention, which it is proposed to establish in London as the successor to the existing Patent Office Library.

International Federation of Operational Research Societies

An International Federation of Operational Research Societies has been created with the objects of developing operational research as a unified science and its advancement in all countries. The initial membership of the Federation consists of the Operational Research Society (United Kingdom), the Operations Research Society of America, and the Société Française de Recherche Opérationnelle. Membership is open to other national societies with the primary object of promoting operational research and with memberships including qualified scientists working in this field. The Federation will be governed by a board of representatives, one representative coming from each member society. According to the statutes, the voting power of each is proportional to the square root of the size of the membership of the Society he represents.

One of the first activities of the Federation will be to sponsor the second international conference on this subject, following the successful first conference held in Oxford in 1957. The second conference is provisionally planned to be held at Aix-en-Provence early in September 1960. Sir Charles Goodeve has agreed to act as secretary and Mr. Donald Hicks as treasurer of the Federation, the address of which is 11 Park Lane, London, W.1.

American Geographical Society Expedition to Chile

The American Geographical Society is sending an expedition to southern Chile for two months study of glaciers in the vicinity of Laguna de San Rafael. Dr. Calvin J. Heusser, of the Society's research staff, will be in charge of the project, which is supported by the Office of Naval Research. Its purpose is to determine the nature and duration of successive phases of climate and vegetation since the glaciers of the last Ice Age receded. The Laguna de San Rafael area was selected because it contains the northernmost glaciers in South America reaching to sea-level and also because its climate, vegetation and physical features resemble those of south-eastern Alaska, where the Society has conducted similar studies since 1948. By correlating the results from Chile with those from Alaska it is hoped that a comparative chronology of climatic variations in the northern and southern hemispheres may be obtained. In addition to Dr. Heusser, the expedition comprises Dr. and Mrs. D. B. Lawrence, both professors of botany in the University of Minnesota; Dr. E. H. Muller, professor of geology, Cornell University; Dr. Carlos Munoz Pizarro, of the Faculty of Agronomy, University of Chile; Shoji Horie, of the Department of Botany, Yale University; and Augusto Grosse, of Puerto Aysen, Chile.

The Atlas Satellite (1958 ζ)

The largest and heaviest satellite so far placed in orbit by the United States was launched in a south-easterly direction from Cape Canaveral in Florida at 23.02 U.T. on December 18. The complete satellite weighs some 8,500 lb., of which only a small proportion, about 150 lb., is pay-load. The remainder of the object is the empty shell of the *Atlas* missile which performed the launching, about 80 ft. long and 10 ft. in diameter. The main purpose of the satellite is to act as a radio relay station, storing and re-transmitting, on frequencies of 132·45 and 139·905 Mc./s., messages sent to it from the ground. It also carries telemetry transmitters operating on 107·97 and 107·94 Mc./s. The satellite is the first to be successfully launched since July 1958, and is designated 1958 ζ. Its orbit is inclined at 32·4° to the equator. Initially, the period of revolution was 101·47 min., and the height varied between 120 and 920 miles, an eccentricity of 0·089; the perigee was near lat. 25° N., when the satellite was on the southward half of its orbit, but the perigee point moved rapidly forward around the orbit, at a rate of 8½° a day. Because its perigee is so low, the life-time of the satellite is expected to be short—only about four weeks.

Giacomo Pylarino (1659–1718)

A pioneer who made variolation a scientific procedure, Giacomo Pylarino was born 300 years ago on January 9, 1659, on the Ionian island Cephalonia. He studied law at Venice and medicine at Padua where he graduated M.D. Practising at Candia in Crete, he made enough money to allow him to travel, and he visited Constantinople, Syria, Egypt, and Smyrna, where he became Consul for Venice. In 1713, Emmanual Timoni, a Greek physician of Constantinople, wrote for the *Philosophical Transactions* an account of the method of variolation as observed and practised by him. Anxious to have further details, Sir Hans Sloane wrote to the British Consul at Smyrna, Dr. Sherrard, who communicated with his former colleague, the Venetian Consul. Pylarino had returned to Venice, but was persuaded to draw up an account of what he knew of the original methods of inoculation at Constantinople during the first years of the century. This was printed at Venice in 1715 under the title "Nova et tuta variolas excitandi per transplantationem methodus; nuper inventa et in usum tracta" and at once copied into the *Philosophical Transactions*. "The most trustworthy account of the Constantinople practice" (Charles Creighton), it dates back to 1701, in which year Pylarino inoculated three children with smallpox virus. He had learned the technique from a Greek woman, but dropped the symbolism, using the skin of the forearm instead of the face at the four points touched in making the sign of the Cross and at the points of the hands and feet pierced by the nails in the Crucifix. It is interesting to note that he spoke of "transplantation" and Timoni of "inoculation"—both figures of speech taken from the gardener's art. Following the publication of Pylarino's description, the Royal Society became really interested in inoculation, and the pages of the *Philosophical Transactions* were filled with further accounts. These were regarded as "virtuoso amusements" (William Douglass) until 1721 when inoculation began to be tried tentatively in London. Pylarino was then no longer living, having died at Padua in June 1718.

City Literary Institute: Science Lectures

A NEW series of lectures sponsored by the City Literary Institute, Stukeley Street, London, W.C.2, and under the auspices of the University of London Department of Extra-Mural Studies, under the general title "Tools of Scientific Discovery: A Review for the Layman and Non-specialist", will begin on January 6, when Prof. G. O. Jones will give an introductory lecture. The other lectures are as follow: "Low Temperatures", Prof. G. O. Jones (January 13); "Radio Telescopes", Mr. Martin Ryle (January 20); "High Temperatures", Dr. R. Latham (January 27); "X-Rays", Dr. H. Judith Milledge (February 3); "Accelerators", Prof. J. Rotblat (February 10); "Isotopes", Prof. J. Rotblat (February 17); "Rockets", Prof. H. S. W. Massey (February 24); "Computers", Dr. R. A. Buckingham (March 3); "Television Techniques", Prof. J. D. McGee (March 10); "Electron Microscope", Mr. C. D. Curling (March 17). The fee for the course is 8*s*. Further information can be obtained from the Principal of the Institute.

The Night Sky in January

NEW moon occurs on Jan. 9d. 05h. 34m. U.T., and full moon on Jan. 24d. 19h. 32m. The following conjunctions with the Moon take place: Jan. 5d. 11h., Jupiter 2° S.; Jan. 18d. 23h., Mars 5° N. In addition to these conjunctions with the Moon, Mercury is in conjunction with Saturn on Jan. 11d. 04h., Mercury being 0·7° S. Mercury is too close to the Sun for easy observation. Venus is an evening star, visible low in the south-west for a short time after sunset. It sets at 18h. 25m. on January 31; its stellar magnitude is − 3·3. Its distance decreases during the month from 170 to 159 million miles. Mars is moving eastwards among the stars and is in Aries throughout January. It sets at 3h. 55m., 3h. 20m. and 2h. 46m. at the beginning, middle and end of the month, respectively. Its stellar magnitude decreases from − 0·6 to + 0·3, its distance from the Earth increasing from 68 to 94 million miles. Mars is in an excellent position for observing during the evening. Jupiter rises at 4h. 25m., 3h. 40m. and 2h. 45m. on January 1, 15 and 31 respectively; it is in Libra. The stellar magnitude of Jupiter is − 1·4; conditions for observation are not very favourable. Saturn is a morning star in Sagittarius, rising at the end of the month at 5h. 30m.; it is too close to the Sun for easy observation. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Jan 1d. 05h. 08·8m., υ Leo. (*D*); Jan. 1d. 05h. 31·2m., υ Leo. (*R*); Jan. 22d. 22h. 09·8m., 26 Gem. (*D*); Jan. 26d. 03h. 04·9m., 6 Leo. (*R*). *D* and *R* refer to disappearance and reappearance, respectively. The Quadrantid meteors are active on January 3; the radiant is near R.A. 15h. 28m., Dec. + 50°. The Earth is at perihelion on January 2, its distance from the Sun being 91·4 million miles.

Announcements

SIR HENRY DALE has been elected an honorary member of the Biochemical Society. Sir Henry is one of the original members of the Society, and the appointment to honorary membership marks not only his distinction as a scientist but also his many years of service to the Society.

MR. EDMUND J. COOPER, who has had extensive experience of the development of voluntary associations, has been appointed general secretary of the Scientific Film Association.

MR. W. A. FERGUSON, of the Director's office of the British Museum (Natural History), has been appointed secretary of the Museum in succession to Mr. T. Wooddisse, who will retire on reaching the age limit on April 1.

THE Institution of Mining and Metallurgy is to make grants in 1959 from the Bosworth Smith Trust Fund to assist postgraduate research in metalliferous mining (excluding mineral dressing but including surveying and geophysical prospecting). Projects may be supported for more than one year. Forms of application can be obtained from the Secretary, Institution of Mining and Metallurgy, 44 Portland Place, London, W.1, before February 28.

THE Council of St. John's College, Cambridge, proposes not later than the end of April 1959 to make an election to the Kenneth Craik Research Award for the assistance of persons engaged in postgraduate research, preferably in physiological psychology. The value of the Award will be £450 a year. It will be tenable from October 1, 1959, for such period, not less than one year nor more than three years, as the Council shall decide. Applications should be sent to the Master, St. John's College, Cambridge, so as to reach him not later than March 14.

THE Bradford Chemical Society, in conjunction with the Department of Chemical Technology of the Bradford Institute of Technology and the Yorkshire Council for Further Education, is holding a symposium on "Radiation Chemistry" on February 13 and 14 at the Bradford Institute of Technology, Great Horton Road, Bradford 1. Further information can be obtained from Dr. W. R. Moore at the above address.

THE British Polarographic Research Society, 55 Oriental Road, Woking, Surrey, is organizing an intensive five-day course in polarography, to be held during January 12–16. Instruction in techniques will be given by specialists from the Technical Advisory Panel of the Institute. Further details can be obtained from the Secretary of the Institute.

THE NUFFIELD FOUNDATION

REPORT FOR 1957–58

IN its thirteenth annual report, covering the year ended March 31, 1958, the Nuffield Foundation records that, of the £8·5 million distributed during the fifteen years of its existence, about £6·5 million has been expended on ventures within the United Kingdom and £2 million in the overseas Commonwealth, of which grants totalling £850,000 were allocated in the year covered by the report. Of this total, about £1·75 million has been in the fields of science and technology, about £1·5 million in that of medicine, more than £1 million on the care of old people and research in aging, and about £1·25 million on social research and experiment and education. The present report places more emphasis than usual on the Foundation's interest in ventures designed to discover the facts relevant to human behaviour and relationships, and an outstanding illustration of this is the investigation into techniques of sampling and questioning which has been in progress since 1949 under Prof. M. G. Kendall at the London School of Economics. The Foundation has now made a grant of £35,000 over five years to enable the Unit to expand its work to include studies of the design of questionnaires, the validation of social inquiries, of interviewer–respondent bias and the motives behind the actual behaviour of people.

During the year the Foundation sought the views of leading biologists on the emphasis of its biological policy at a week-end conference at Tunbridge Wells, and the Foundation afterwards decided that biology should remain a major interest, not only because biological research is making its expected contributions to medicine and agriculture, but also because it is indicating the growing points in other disciplines, particularly chemistry. Accordingly, the Foundation will support work which promises to lead to a new understanding of biological processes, and the report refers particularly to the Foundation's interest in new developments in the analysis of synthetic systems, the control of enzymic synthesis, and the sequence of events that link particular nuclear components with the organization of the cell. In psychiatry it is interested in studies of behaviour and learning that throw light on the mechanisms involved, and it will continue to be interested in instrumentation, both for resolving existing biological processes and for the possible development of new techniques.

In accordance with this policy, a major grant of the year was £34,000 for the construction of an analogue computer at University College, London, resembling the nervous system of an animal, which will be trained to recognize shapes held in front of its model eye. The new computer, which is the outcome of Prof. J. Z. Young's work on the physiology of learning, should be able to simulate the learning of the alphabet and the numerals and a limited number of more complex shapes, which might include human faces. The Institute of Experimental Psychology, University of Oxford, has also received a grant of £10,000 over three years and nine months towards Dr. N. S. Sutherland's investigation of the mechanisms by which animals and human beings analyse stimuli and, in particular, how visual shapes are analysed. Two grants of £1,980 over three years and £900 over three years were made for investigations at the University of Reading on the structure of optic ganglia of the locust and their connexions and on the brain of the wood ant. A grant of £2,800 over two years was made towards Dr. K. E. Machin's work on physical aspects of behaviour, and a grant of £1,500 a year for two years to University College, London, was in support of three studies which are part of general research into the causes and treatment of mental deficiency: the search for rare or hitherto unknown cases of metabolic disturbance; dietetic experiments with selected amino-acids in cases of metabolic anomaly; and clinical trials of biologically active substances.

A grant of £15,000 over five years was made in support of Prof. B. Katz's work at University College, London, on nerve cells and muscle fibres, and further support of up to £1,500 a year for three years is being provided for Prof. J. Baddiley's work at King's College, Newcastle upon Tyne, on the chemical structure of bacterial cell walls. A programme of research into the effects of radioactive fall-out on wild animal population being undertaken by St. Bartholomew's Hospital Medical College is being supported by a grant of £3,200. A grant of £4,884 over three years was offered for a study of hybrid vigour at University College, London, and £800 a year for two years towards one of the acetate metabolism by *Chlorella*.

Towards Dr. J. D. Biggers's work at the Royal Veterinary College, London, on the growth of embryonic bones on chemically defined media, a grant of £3,200 over five years was offered, and one of £6,000 over three years was made to University College, London, in support of investigations on the mechanisms of processes catalysed by enzymes. For studies of pregnancy toxæmia and scrapie and myopathy in sheep at the Nuffield Institute for Medical Research, Oxford, a renewed grant of £7,500 for two years was made, and one of £6,500 over three years for research into the bacteriology of calf diarrhœa at the Royal Veterinary College, London. £12,000 was offered to the Marine Biological Association of the United Kingdom for the complete reconstruction of its aquarium. £2,200 a year for five years was given to the British Trust for Ornithology for a centre to collate, analyse and file the pooled data of bird observatories and to prepare reports. Up to £2,350 over three years was offered to the University of Glasgow for studies on the effects of physical and biological factors on spawning, while two interesting minor grants of £1,000 were made, one to Marlborough College towards the cost of apparatus needed for actual research into the magnetic susceptibilities of materials, and the other to the University of Leeds for the production of a series of films presenting the development of scientific ideas in a form suitable for sixth forms and undergraduates.

Besides administering the Oliver Bird Fund, the Foundation contributes an equal sum for fundamental and clinical research into the causes and cure of rheumatic diseases. Experience of the past four years points to the need for more centres specializing in rheumatism if more rapid progress is to be made.

Two problems in giving effect to such a policy are how to attract more clinicians into rheumatology and how to stimulate the interest of the pure scientist in the study of fundamental problems which may bear on rheumatism. Hope is expressed that work will soon begin on the difficult problems of what controls the behaviour of the fibroblast and what are the enzyme systems involved. Of four new grants in this field during the year, three have been given to centres already supported by the Foundation; the fourth, of £4,000 over two years, was to the Institute of Orthopædics for research on the constituents of cartilage. The controlled clinical trials of cortisone and allied hormones suggest that both prednisone and prednisolone are superior to cortisone in the treatment of rheumatoid arthritis and that there may be some fundamental difference between the action of these two steroids and cortisone. Of other grants for medical research may be mentioned one of £80,000 to endow a chair in child surgery at the University of London; up to £2,000 to the University of Leeds towards the cost of acquiring a Skeggs Leonard type of artificial kidney for comparison with the Merrill type; £2,250 a year for three years and a capital grant of £300 to the Institute of Neurology, University of London, for a long-term clinical investigation into the effects of hypotensive drugs and anticoagulant therapy in the treatment of cerebrovascular disease; a further grant of £10,700 over two years to the Tuberculous Meningitis Unit, United Oxford Hospitals, for research on disseminated sclerosis; up to £12,000 towards the cost of adaptations to the Pioneer Health Centre, Peckham, for a diagnostic centre for local doctors; and £2,520 a year for three years to the Institute of Psychiatry, University of London, for work on cutting the pituitary stalk.

Among the grants for the care of old people and research in aging are one of £2,500 to the National Institute for Adult Education for a comprehensive inquiry into existing educational facilities for the elderly, the use made of them, and the general role of adult education in helping people to adjust themselves to retirement and to continue leading an active life; £3,000 for a pilot study into the economic circumstances of people over retirement age; £2,000 over three years to the University of Exeter for an investigation into the effects of aging on the performance of tasks of varying complexity; and a further grant of a five-year fellowship rising from £1,500 to £1,700 a year to Dr. A. Comfort for his long-term investigations at University College, London, into the aging of fish and the pattern of aging in dogs and thoroughbred horses, which may yield information on the inheritance of longevity and the effects of parental age.

Other grants for social research and education during the year include: £6,850 over three years in support of a study of the social composition of a Lancashire industrial town, which will comprise an analysis of the number and functions of the professional, managerial and administrative groups and their role in the life of the community, and a study of the working-class population and its part in political and associational life and the relation of local to national culture. This study is being conducted by the Department of Social Anthropology and Sociology, University of Manchester.

A brief summary is given of the first part of Mr. J. Trenaman's study of the educational possibilities of radio and television, newspapers and films, towards which a further grant of £500 has been made. Broadcasting and the Press are the only contemporary influences that can reach across a majority of the population to the fringes of the 45 per cent that are resistant to education in its broader sense, and Mr. Trenaman thinks they could do more to stimulate critical thinking.

SCIENTIFIC BASIS OF LAND PLANNING IN THE TROPICS

An inescapable problem of the present-day world is the increasing pressure of population on land resources. Widespread knowledge and practice of death control have overtaken birth control so that, one by one, the countries of the world are experiencing the problem of how to match expanding population with expanding food production. The problem has now hit the Gambia, and in facing it the Gambian Government, perhaps influenced by the salutary lesson of the failure of the poultry scheme, is wisely realizing the fundamental need for a basis of factual knowledge on which to plan its land use and land planning policy. Rather more than a hundred and fifty years ago Britain, faced with the imminent possibility of a Napoleonic invasion, realized the need for adequate maps and set up the Ordnance Survey.

To-day, the far-flung parts of the Commonwealth face crises of many different types, and the Directorate of Overseas Surveys has been charged with the Herculean task of providing at least a skeleton map cover as a basis of operations. The maps the Directorate is producing are for the most part on a scale of 1 : 50,000 and are based essentially on air photographs. At the same time, the air photographic cover provides a wealth of other information, notably that of present land use. There are special reasons for using this information to prepare a series of land use maps* of the Gambia on the scale of 1 : 25,000. The sandy leached soils in the past have been worked on a system of bush fallowing but produce only indifferent crops of sorghum, millet with some cassava and maize and groundnuts as a cash crop, and a little upland rice. With increased population the period of fallow is so shortened that the soils do not recover and the system breaks down. With Government aid, attention has been turned to the clearance of mangrove and grass swamps bordering the Gambia River and the cultivation of their heavy clay soils for rice. This is more revolutionary than it sounds, because, traditionally, the women have cultivated the land; but swamp clearance, construction of bunds and causeways and mechanized ploughing are man's work. The policy has apparently been successful: the reclaimed areas can be pointed out with pride; the old 'hungry season' of March–April seems to have disappeared. Yet rice imports are increasing. Can it be that as new areas are reclaimed, equally large areas of upland are being abandoned ? Unfortunately, there are no map records, and we see here the inadequacy of statistics where a complete shift in cultivation from one part of an administrative unit to another would not appear at all in any statistics of land use. There could, indeed, be no clearer demonstration of the complementary character of cartographic and statistical–economic interpretation of data, or the inadequacy of the latter without the former.

---

* Directorate of Overseas Surveys. Gambia Land Use Map, Sheet 12/1: Janneh Kunda. Gambia Land Use Map, Sheet 14/11: Mansa Konko. (Scale 1 : 25,000.) (Tolworth: Directorate of Overseas Surveys, 1958. Obtainable from Edward Stanford, Ltd., 12 Long Acre, London, W.C.2, and the Survey Department, Bathurst, Gambia.) 3*s.* 6*d.* each.

The work in the Gambia has been carried out under the direction of Mr. Martin Brunt, land use officer of the Directorate of Overseas Surveys, working on air photographs coupled with three periods on the ground for vital checking. He used series of photographs taken in 1946 by the Royal Air Force and another series taken in 1956 by Aircraft Operating Co. (Aerial Surveys), Ltd. The fully coloured maps are able to show, therefore, the extension or retraction of rice lands.

It is characteristic of tropical agriculture that the intricate pattern of land use is apt to defeat the cartographer even on large scales. Gambia is no exception. In the two published sheets out of the projected thirty-five sheets for the central Gambia, six colours are devoted to cropland, three being for rice according to the proportion of the land cultivated—the actual plots are too small. The tidal flats show a complex mixture of high and low mangrove and grass marshes with a little 'barren marsh'. On high ground a distinction is made simply between 'woodland', 'fallow bush' and grass.

In due course an explanatory memoir is promised—no conclusions are drawn at this stage. In the meantime, there can be nothing but praise and admiration for all concerned: a far-sighted Government for commissioning a survey and the publication of a factual document in the form of maps which cannot fail to be of permanent value for all time; a technically excellent publication; and a land use officer who understands clearly the problems involved.

A somewhat similar problem in a still more acute form is presented by the island of Singapore. More than a million and a half people are crowded into an area the size of the Isle of Man. The urgent questions are largely those of town planning, but there are patches of land excellent for intensive market gardening, producing much-needed fresh vegetables for the local market; there are light lands with excellent coconut groves; and, though pineapples have been ousted and rubber is being squeezed out, poor soils remain in second growth scrub protecting water supplies. There are swamp lands inviting reclamation, and once again a careful record and understanding are vital. In this case the mapping is being carried out by the University of Malaya. The survey tradition established in the Department of Geography by Prof. E. H. G. Dobby (now of Ghana) is being ably continued by Robert Ho, Paul Wheatley and their team, and the first sheet* out of ninety-four projected on the scale 1 : 6,336 (10 in. to the mile) has just been published for the Singapore Improvement Trust. Some twenty categories of rural land use are shown, and in addition urban land uses are fully delineated. Like the map of the Gambia, this constitutes a factual document of utmost and lasting value. By showing things as they are and then in the explanatory memoir which is in preparation attempting an explanation, we are led away from that dangerous short cut of mapping 'land capability classes' decided so frequently on inadequate knowledge and based inevitably on a subjective judgment with present-day conditions in mind.

L. Dudley Stamp

EUROPEAN ORGANIZATION FOR NUCLEAR RESEARCH

REPORT FOR 1957

THE third annual report of the European Organization for Nuclear Research* (CERN) covers the period to the end of 1957 and includes a list of the twelve member States of the Organization; their percentage contributions to the budgets for the years 1957, 1958 and 1959; details of the structure and membership of the council; and a list of the names of the senior staff of the Organization.

During the period under review, the constructional work on both the proton synchrotron and the synchro-cyclotron accelerators and the buildings on the Meyrin site has progressed according to schedule. The 600-MeV. synchro-cyclotron came into operation on August 1, 1957, and already an interesting programme of research under the supervision of Prof. M. Bernardini, the research director of the Synchro-cyclotron Division, has commenced. Details of the construction and testing of the accelerator are given in a separate section of the report. They include the investigation of properties of the internal proton beam; the installation of the several beam-bending magnets; the construction of the final shielding wall to give protection against neutrons; and the fitting of appropriate channels for mesons and neutrons. The Proton-synchrotron Division has passed the design, planning and ordering stage, and has entered upon the active phase of the construction of the machine and of its ancillary equipment. The whole Division, consisting of 165 staff members engaged on the design and construction of the synchrotron and nine Fellows in the research group studying new ways of accelerating particles, is now installed at Meyrin, and the old offices and laboratories at the Institute of Physics in Geneva have been vacated. The first scheme to be studied by the research group was the plasma ring accelerator proposed by Budker at the CERN Symposium in 1956. Both theoretical studies and experimental studies with an air-cored betatron have been carried out. It is expected that the experiments will indicate the general utility of plasma ring discharges as accelerator guide fields.

The offices, laboratories, experimental halls and the ring complex are all finished and occupied by

R 315

the Proton-synchrotron Division, and apart from minor installations and some road work, there remains only the power house, containing the magnet generators, water-cooling apparatus and electrical sub-station for the whole machine, to be completed. Consideration has already been given to the research programme for the 25-GeV. machine, which is planned to become operational in 1960. At an energy of 25 GeV. the usual methods of particle analysis and detection break down, and therefore a preliminary period devoted to the study and development of the necessary large and expensive experimental equipment required is desirable. A short list of nine typical experiments which has been drawn up is given in the report.

Unlike the accelerator divisions of the Organization, the Theoretical Study Division is not bound to follow a construction time-schedule, and its scientific output has already been considerable. It will, however, be greatly stimulated when the experimental groups become fully operative, for then it will enjoy the benefit of obtaining its data at source. The Division is mainly concerned with the investigation of the so-called elementary particles, their number, structure, properties and interactions. The lists of publications originating from the Division, and the colloquia held at the Institut de Physique in Geneva until June 19, 1957, and at the Meyrin site until the end of the year, together with the lectures and colloquia of the Division at Copenhagen, are given in appendixes to the report. The number of members of the Division greatly increased during the year and included senior physicists from non-member countries who were able to pursue their studies in the Organization's laboratories through grants provided by the Ford Foundation.

In the Scientific and Technical Services Division, the main spheres of development of experimental techniques were liquid-hydrogen bubble chambers and electronic evaluation of track photographs. In addition, a health physics section was started, and the Division continued to administer the Scientific Information Service and the Cosmic Ray Research Group.

The hydrogen-liquefying plant mentioned in last year's report was installed in the summer of 1957 and liquid hydrogen was produced for the first time in July 1957. The plant produces about 32 litres per hour. The 10-cm. bubble chamber was completed during the year, and an illustration of it, together with photographs of other equipment, is included in the annual report.

THE AUTOMATIC COMPUTING ENGINE AT THE NATIONAL PHYSICAL LABORATORY

THE Automatic Computing Engine, or ACE, is the latest digital computing machine to be built at the National Physical Laboratory for the use of its Mathematics Division. This new machine, with its increased speed of operation, its larger storage capacity and its many additional functional facilities, is a considerable advance as a computing tool on its predecessors, the experimental pilot-model, ACE, and its engineered counterpart, DEUCE.

It is not easy to assess the speed of a machine from the times taken to carry out the elementary arithmetical and logical operations. This is particularly true of any machine with a high-speed store of less than about 8,000 words, on which many problems will demand the use of the backing-up store. The times taken for a few basic computations probably give as accurate a picture of the overall speed as can be obtained without a detailed study.

(1) The zeros of a polynomial of the 16th degree may be obtained in an average time of 15 sec. Because of the long word-length (48 digits), accurate roots even of very ill-conditioned polynomials of this degree will be obtained. Polynomials of degrees up to about 250 may be found without using the drum-store, though no particular loss in speed results from using the drum on such problems.

(2) A set of simultaneous equations of order 30 can be solved in about 5 sec. Even if none of the coefficients is zero, sets of orders up to 170 may be solved, the time taken varying approximately as the cube of the order but being slightly less for higher orders.

(3) The solution of Poisson's equation, $\nabla^2 V = 4\pi\rho$ on a square with 400 mesh points, may be obtained in about 75 sec. This time is for the direct solution of the finite difference equations and will give values correct to at least ten decimals. After solving one such problem, solutions corresponding to different distributions of ρ may be obtained in about 15–20 sec. each.

ACE is a serial computer in which numbers and instructions have 48 binary digits; the digit-rate is 1·5 million per second, and therefore its word-time or minor cycle is 32 microseconds.

The main working store consists of twenty-four mercury delay lines each containing thirty-two words, circulating in a major cycle of 1,024 microseconds. Rapid-access storage is obtained by using mercury delay lines with capacities of one, two and four words. The backing store consists of four magnetic drums containing a total of 32,768 words.

The ACE instruction specifies a three-address operation of the form '*A* function *B* to *D*', where *A* and *B* are the store-addresses of the operands and *D* is the store-address to which the result of the operation is to be sent. Instructions also specify a further store-address, *N*, from which the next instruction is to be extracted. The time needed to execute this operation (for single-length numbers) is 32 microseconds, and since each operation may be followed immediately by another, a maximum rate of operation of 30,000 per second is possible.

The drum-store, the multiplier and the divider are independent units. These are put into operation by the appropriate instructions and then work independently until they have completed their operation. This feature provides a parallelism of operation, since a multiplication, division, drum-transfer and a series of ordinary operations could be in progress at the same time.

The three-address operation of the machine allows the multipliers and multiplicand to be selected and the multiplication process to be initiated by a single instruction. The product is formed in fourteen minor cycles, that is to say, in 430 microseconds. The division process is similarly specified, and the quotient (rounded or unrounded) is formed in approximately 1·5 milliseconds. The divider also contains an automatic standardizing process for use in floating-point arithmetical operations.

The magnetic drum-store has a total capacity of 1,024 long delay lines, that is to say, about 1·5 million digits. There are four drums each having 256 tracks, each track storing the contents of one delay line. Each drum has sixteen read heads and sixteen write heads, the 256 tracks being obtained by moving the heads as one unit into one of the sixteen discrete positions. Each drum is 6·75 in. long by 5 in. in diameter, allowing a linear digit packing of 100 per in. The drum is driven by a hysteresis motor running synchronously at 12,000 r.p.m. and is phase-corrected so as to rotate exactly once in five major cycles of the machine.

Punched card and magnetic tape equipment will be provided for input and output. The installation will initially consist of two machines: (1) a broadside card reader, running at 450 cards per min.; (2) a broadside card punch running at 100 cards per min. In order to read or punch 80 columns of a card the computer has an 80-digit input dynamicizer and an 80-digit output staticizer.

The ACE has been designed and constructed to allow easy maintenance. Extensive marginal checking facilities are provided and the chassis units are designed to give complete accessibility to all components, valve connexions, etc.

The machine is housed in ten cabinets, each having a cooled air-circulation system. Each cabinet is fitted with a rising door which permits immediate access to all the twenty-four chassis units contained therein. The number of valve envelopes is about 6,000.

D. W. DAVIES

THE ADÉLIE PENGUIN

DETAILED observations of the Adélie penguin, *Pygoscelis adeliae*, have been carried out by Dr. W. J. L. Sladen of the Falkland Islands Dependencies Scientific Bureau and the Edward Grey Institute, University of Oxford[*].

The Adélie is antarctic and circumpolar in its distribution, but does not breed north of the South Sandwich Islands and Bouvet Island. It is the most abundant and widely distributed of all the antarctic penguins.

Two rookeries were studied between 1948 and 1951, one at Hope Bay, Graham Land, and the other at Signy Island, South Orkneys. At both of these there survived a small number of birds that had been ringed two seasons before. The only certain way of determining the sex of these penguins, other than by dissection, is to mark breeding birds before egg-laying and to continue observing them during the early part of the breeding season. Casuals and non-breeders cannot be sexed unless marked and recovered breeding in another season.

The diversity in behaviour of a penguin community appears to be due to three factors which are often inter-related: variation among individuals, differences in 'intensity' of behaviour, and differences in age and breeding experience. Emphasis is laid on the differences in age and breeding experience, and some evidence is given from field observations and dissections to show that this is an important factor.

Suggested age-groups divide a population seen at the rookery into five categories: the experienced (established) breeders, the inexperienced (unestablished) breeders, the non-breeders ('wanderers') in adult plumage, the non-breeders in immature plumage (yearlings), and the nestlings.

The established breeders, probably four or five years old and more, come back to their former nest-sites independently of their former mates. Such a bird may 'keep company' with another bird of the opposite sex until its true mate returns.

The unestablished breeders have first to establish themselves and pair off. Their behaviour differs somewhat from that of the established birds, though with some overlap due to individual variations. They often arrive back later than the established breeders, and take up territories on the periphery of the colonies, or fill vacant places within them. They are the cause of most of the fighting. Courtship behaviour is more prolonged, egg and chick mortality higher and breeding efficiency lower.

The non-breeding 'wanderers' in adult plumage are two or three years old and can be seen wandering around the rookery in small parties, and even visiting rocky outcrops up to 1,000 ft. above sea-level far away from the breeding area. Some of them build poor nests, or occupy vacant sites for a short time before moving elsewhere or being turned out by older birds. Of the wanderers which were dissected, some showed undeveloped gonads despite their adult plumage. It is this age-group which, together with some of the unestablished birds, under favourable conditions, occupy new ground and thus extend the range of the species. They will also quickly take the opportunity to fill any gap in the colonies, and may during the re-occupation period occupy territory in anticipation of the following season.

The yearlings, which are easily recognized by their white throats, normally live among the pack ice, but are occasionally seen at the rookery, where they associate with the wanderers. Several were seen building nests in a half-hearted way on the edge of colonies; but, like the wanderers, they never stayed in one place for long.

Describing the displays and postures of the Adélie penguin, Sladen shows that during the first and second fasting periods the ecstatic display is confined to the male, its most important function appearing to be in pair-formation. A lone male by this display can attract a nearby female to its nest. After the eggs have hatched (or should have hatched), it is also seen in females, though on a diminished scale. It is more commonly seen among the younger and unestablished breeders or non-breeders than among the established breeders.

---

[*] Falkland Islands Dependencies Survey. Scientific Reports, No. 17: The Pygoscelid Penguins. 1: Methods of Study. 2: The Adélie Penguin *Pygoscelis adeliae* (Hombron and Jacquinot). By Dr. William J. L. Sladen. Pp. i+97+12 plates. (London: H.M. Stationery Office, 1958. Published for the Colonial Office.) 47*s*. 6*d*. net.

The 'bill to axilla' display, here described for the first time, appears to be closely related to the ecstatic and is probably also associated with pair-formation. Its resemblance to one of the attitudes of threat suggests that this display has in it a greater element of repulsion for the same sex and less attraction for the opposite sex than has the ecstatic. A possible relation to nervous strain of the ecstatic and 'bill to axilla' displays in some situations is suggested.

Bowing is believed to be both a posture and a display, and it is suggested that the display is associated with early pair-formation, and is possibly a form of appeasement ceremony.

Both sexes share the duties of nest-building. The Adélie's habit of stealing stones suggests that it serves a useful purpose in distributing stones throughout a colony from the outside towards the centre, thus reducing the necessity for long treks.

The breeding season starts when birds return to the rookeries in September and October and occupy nest-sites. They may have to travel 200 miles or more from their winter quarters, the last stage being over many miles (up to sixty) of rough sea ice. The occupation period is the period from arrival until the last egg has been laid. Evidence is given from marked birds that, once established, Adélies are, on the whole, very faithful to their old nest-sites from year to year, and keep the same mates. Nest-sites are often covered by a foot or more of snow, yet Adélies appear to come back to the same spot.

The normal clutch is two eggs, the interval between the first and second being 2–4 days. If eggs are removed as soon as laid, a third one is sometimes produced. Adélies are single-brooded. The average incubation period (from the day of laying until the chick is completely out) is thirty-five days with a range of thirty-three to thirty-eight days.

The care of the young is divided into three stages: the guard stage when one of the parents is at the nest to care for and feed the chicks while the other is away collecting food; the crèche stage, when the chick is left alone at an age of about 4 weeks and groups with others to form crèches of 100 or more chicks, and, later, the dispersal of the crèches. Evidence is given from a study of marked adults and chicks that parents feed their own chicks in the crèche, feeding others only in exceptional circumstances. There are no adult 'guardians' of the crèches. These two facts are contrary to previous accounts of penguins the chicks of which group together in crèches.

The Adélie's habit of 'keeping company' (that is, the partnership of two birds of opposite sex at a nest-site which may, or may not, lead to the establishment of a mated pair) is believed to have survival value in facilitating the formation of new pair-bonds should the original mate of an experienced breeder fail to return, or return very late.

Most Adélies moult away from the rookeries among the pack ice. The yearlings moult first. Little is known about the winter movements of the Adélie, but the birds appear to stay in the pack ice and visit land in winter only when gales break up the fast ice and bring the pack close to land.

REINFORCED PLASTICS

A CONFERENCE on reinforced plastics, organized by the British Plastics Federation, was held in Brighton during October 22–24. Twenty-four papers were presented, and a morning was devoted to short talks by representatives of industries which use plastic components.

For structural purposes, high polymers in bulk form are inadequate in strength and stiffness. After surface imperfections have been removed by acid polishing, bulk glass has great strength, of the order of 250,000 lb./in.^{2}, but it is structurally unsuitable, because of the ease with which the surface is damaged and because of the low average stress at which cracks are propagated from regions of damaged surface. By subdividing the glass into fine fibres, and bonding these together with a polymer, a useful two-phase structural material is obtained which is readily shaped during manufacture and which has high resistance to the propagation of cracks. The glass fibres are used in the form of rovings, chopped strand mat or woven fabrics. The polymers are usually polyesters or epoxides which have suitable mechanical properties at temperatures up to 150° C. Silicones are used where parts are required to operate at temperatures above 150° C., and they retain useful strength properties up to 250° C.

Typical strength data for polyester glass sheet materials at room temperature are given in Table 1.

Table 1

Reinforcement	Bidirectional glass fabric	Unidirectional glass fabric	Glass mat
Percentage glass by weight	60–65	62–67	30–45
Tensile strength (lb./in.^{2} × 10^{-3})	40–50	78–86	10–24
Young's modulus (lb./in.^{2} × 10^{-6})	1·0–2·8	4·0–5·0	1·0–2·0

Polyester and epoxide resins are first prepared as linear polymers, containing double bonds; at this stage they are viscous liquids. During preparation, water of condensation is removed. The linear polymers are then cross-linked using a monomer such as styrene or dicyandiamide. Cross-linking is achieved with the aid of a catalyst and may occur at room temperature or at an elevated temperature. Little condensation product is produced and little pressure is necessary.

There is at present little knowledge of the nature of the interface between glass and polymers. Glass is normally covered with a film of moisture in which soluble constituents of the glass dissolve. This film may prevent adhesion to the polymer or inhibit polymerization locally. Various finishes, of which vinyltrichlorsilane is an example, are available for application to glass; by reacting with the moisture film, these are thought to become chemically bonded to the silica in the glass, and to present an unsaturated hydrocarbon surface for adhesion to the polymer. The treatment of glass fibres with such finishes yields a more durable plastic under wet conditions, but there is not yet sufficient experience to enable a reliable assessment to be made of long-term durability. At the conference it was reported that a set of unstressed polyester–glass test pieces showed no deterioration in strength after exposure to English weather for two and a half years, and static-water tanks of the same material have now been in use for the same period with little apparent deterioration.

When loaded to higher stresses, test pieces subjected to cycles of wetting and drying and to increase and decrease in temperature show deterioration in properties. Epoxides are generally superior to polyester under such conditions. Further research is necessary to produce a better understanding of the nature of the deterioration.

The behaviour of plastics reinforced with glass under cyclic loading is interesting. Glass alone withstands a cyclic loading for about the same time as it withstands a steady load equal to the maximum occurring during the cyclic loading. This delayed fracture under steady load is known to be caused by attack of the atmosphere. With plastics reinforced with glass, once the adhesion between glass and polymer has failed, atmospheric attack can take place, especially if the polymer has crazed; but deterioration under cyclic loading may also be associated with damage to the glass surface when it slides in the polymer matrix or rubs against another fibre and with local non-uniformity of the distribution of load among the fibres.

Plastics reinforced with glass fail under cyclic loading in a shorter time than would produce failure under static loading of the same intensity. They therefore display a definite fatigue effect as well as delayed fracture. The relatively high resistance to propagation of cracks is shown by cyclic loading tests on notched test-pieces. For a given notch and nominal stress cycle, the number of cycles to failure may be higher for the plastic than for aluminium alloy.

In plastics reinforced with fibre, each fibre contributes to strength and stiffness only in the direction of its length, and it has been calculated that a two-dimensional isotropic mat of fibres should have strength and stiffness equal to one-third of that of the longitudinal strength of an array of parallel fibres. In principle, glass flakes, if of equal breaking stress, should form a sheet material three times as strong and stiff as a material reinforced with fibre. Preliminary experiments with glass flake material reported at the conference showed considerable increase in stiffness, but the expected increase in strength was not achieved, probably because of damage at the edges of the flakes.

Originally developed for aircraft radomes, plastics reinforced with glass are finding increasing application in a wide variety of components. These include boats (including ship's lifeboats), car bodies, bus and railway wagon-tops, translucent building panels, ventilation ducting, tanks for the chemical industry, partitions for aircraft and ships, and jigs and press tools. Their development has been a co-operative effort of physicists, chemists and engineers. Their further development will depend on the invention of stiffer glass, of resins more stable chemically and on research into the mechanism of deterioration and fracture.

C. GURNEY

WHEAT GENETICS

DURING the ninth International Congress of Genetics, held at Bellagio in 1953, a small group of participants resolved to organize in the future special meetings at which the objects, results and techniques of current research in wheat cytogenetics could be discussed, and at which workers in the field could be brought into personal contact. As a result, the first International Wheat Genetics Symposium was held during August 10–15 at the University of Manitoba, Winnipeg, Canada. Some 150 participants from twenty-nine countries assembled to join in the formal sessions and in informal discussions, and to see something of the famous wheat-growing region of Manitoba.

The formal meetings were held under the general chairmanship of Dr. H. Kihara (Japan), who, in his opening remarks, recollected that it was exactly forty years since the correct chromosome numbers of the polyploid series in wheat were determined by Sakamura and by Sax. The intervening years had seen intensive research in the sub-tribe Triticinae, and this work had contributed to making the cytogenetic composition of common wheat, *Triticum vulgare*, better understood than that of any other polyploid species. Among the themes of the symposium were some of those which have been most prominent over the years in wheat cytogenetics, notably the investigation of the inheritance and the utilization of disease resistance, the study of the genetic make-up of wheat using aneuploids and the study of interspecific crosses.

In distilling the essence of many years of research into the application of backcrossing to plant breeding, and particularly to breeding for disease resistance, Dr. F. N. Briggs (United States) emphasized that these methods could only be applied when suitable recurrent parents were available and where improvement was required over only a limited sector of the total range of genetic variation. Combination of backcrossing with any other method, although sometimes necessary, meant departing from the security of a tested genotype.

Backcrossing is being used by Dr. N. E. Borlaug (Mexico) to produce multi-line varieties of wheat designed to combat stem rust, the biggest single disease hazard to world wheat production. Numbers of different rust resistant parents are backcrossed into a common, generally useful, but rust susceptible, recurrent-parent variety. When the recurrent variety has been reconstituted in each backcross line to such an extent that there is little difference between them, except the source of their disease resistance, seed of the lines can be mixed in various proportions to form multi-line varieties. Since the multi-line variety includes several genetically distinct types of disease resistance, it is likely that during a rust attack some of its component lines will be resistant to the prevalent races of the pathogen. The risk of catastrophic crop failures will therefore be minimized, both on account of the yield returned by the resistant lines and because the lower proportion of susceptibles will limit the build-up of the epidemic. The actual composition of a variety may be changed from time to time to counteract altered frequencies of rust races, and as many as eight lines may need to be included in one variety. The first trials suggest that even in the absence of disease there may be some advantage in growing the multi-line varieties primarily designed to restrict rust.

The importance of developing the disease resistance, and especially the rust resistance, of the wheat crop was underlined by two further contributions. Dr. D. R. Knott (Canada) has analysed twenty-nine varieties of wheat in which he has discovered seven different genes governing stem rust resistance. Some varieties had no genes for resistance, others had up to four, and moreover the genes differ in the level of resistance conferred and in their dominance relationships. By monosomic analysis, the chromosome on which each gene is carried has been determined, and now each gene is being separately studied, in the absence of all other genes for resistance, in a common genetic background. Dr. Knott's work, in conjunction with information on the spectrum of race reactions due to each gene, permits a more rational approach to the utilization of sources of rust resistance in breeding programmes than has previously been possible.

Indeed, this work comes part way to meeting the wishes of Dr. A. R. de Silva (Brazil), who pleaded for a more precise identification of genetic variation in the host and pathogen as a preliminary to the scientific incorporation of rust resistance in breeding material. He considered that host–pathogen relationships should be envisaged in terms of genes for resistance versus genes of pathogenicity, rather than in terms of rust races versus varieties differing in race response.

In discussing these papers, Dr. E. C. Stakman (United States) proposed that resistance was perhaps not simply attributable to single genes, since it depended on the overall physiology and morphology of the plant. Disease resistance was also among the criteria on which Dr. R. de Vilmorin (France) and Mr. H. C. Thorpe (Kenya) placed considerable value in breeding new wheat varieties for their own areas, but both emphasized that overall suitability of varieties was essential, and that this could not be neglected for the sake of particular characteristics.

T. vulgare is extremely tolerant of many aneuploid conditions in a way which forces recognition of the close genetic relationship between the three genomes of which it is composed. Dr. E. R. Sears (United States) has been prominent among those who have exploited the tolerance of aneuploidy in the cytogenetic analysis of wheat. His work commenced with the development of the twenty-one lines monosomic in turn for each of the chromosomes of wheat. By using the monosomic series in crosses with euploids in other varieties it has been possible to analyse some of the genetic differences between varieties. Additional genetic knowledge was obtained from studies of the nullisomic derivatives of monosomics. The seven homœologous groups of three chromosomes representing the equivalent chromosomes of each of the three genomes of wheat have been established by nullisomic–tetrasomic compensation, and the chromosomes in each genome have been determined by crosses of monosomics to stocks deficient for one or other complete genome. Dr. Sears's monosomic series has provided the basis for extensive aneuploid work in Canada which Dr. J. Unrau (Canada) reviewed. Monosomic series have been developed in more than eight wheat varieties, and some genetic analysis of disease and insect resistance and of certain morphological characters has been accomplished. The genetic breakdown of polygenically inherited characters by aneuploid techniques has now commenced. In the Canadian work the reciprocal exchange of intact chromosomes between varieties is a new source of genetic information, a striking example of which is that the substitution of a particular chromosome pair from another variety may increase the yield of the recipient variety by 50 per cent.

The extent of the genetical duplication, or triplication, in hexaploid wheat was stressed from results with induced mutations in diploids, tetraploids and hexaploids by Dr. J. Mac Key (Sweden) and by Dr. S. Matsumura (Japan). This underlined the pronounced triplication of genetic material which is indicated by the recognition of the homœologous groups by nullisomic–tetrasomic compensations. A puzzling problem has been to reconcile genetic triplication of this order with the purely diploid form of meiosis found in *T. vulgare.* However, Dr. R. Riley and Dr. G. D. H. Bell (England) were able to present evidence, confirmed by Dr. Sears, that the cytologically diploid behaviour of hexaploid wheat is controlled by genes on one chromosome, in the absence of which there is pairing between equivalent, homœologous, chromosomes of the different genomes. Thus, genetical triplication in hexaploid wheat can be associated with high fertility and genetical stability because of a genotype which imposes a bivalent-forming regime.

Aegilops squarrosa, the species which contributed the *D* genome of *T. vulgare*, would not be chosen by most plant breeders as a parent in a breeding programme. Yet its chromosomes are undoubtedly present in common wheat; a circumstance which Dr. L. Shebeski (Canada) considers may limit the advances to be made by breeding within the species. Consequently, he and Dr. B. C. Jenkins are producing entirely new sets of seven chromosomes, less restricting in gene content, to replace the *D* genome. The very vigorous amphiploids between tetraploid wheat and rye were made with similar objects by Dr. E. Sanchez-Monge (Spain), and their derivatives may have practical value in certain marginal environments where rye is at present the only suitable cereal crop.

The difficulties of handling the concepts of genome analysis were described by Dr. H. Gaul (Germany), and other considerations in the study of polyploids were discussed by Dr. R. Riley and Dr. G. D. H. Bell (England), who compared the behaviour of a range of synthetic amphiploids with that of related natural polyploids. This work includes studies on the cytogenetics and breeding value of lines in which single pairs of rye chromosomes are added to the full complement of wheat chromosomes, or in which a single pair of wheat chromosomes is replaced by a single rye pair.

The conservation of natural variation in an economically prominent group like *Triticum* is clearly an important consideration, and the maintenance of collections of varieties potentially useful in breeding programmes was described by Dr. J. B. Harrington (Food and Agriculture Organization, Rome) and by Dr. L. P. Reitz and Dr. D. J. Ward

(United States). However, as Dr. A. T. Pugsley (Australia) pointed out, no system was in existence to co-ordinate the maintenance of wheat material of experimentally determined genetic constitution, and one of the practical accomplishments of the symposium was the formulation of a scheme to do this.

A useful session dealt with the application of the induced mutations to plant breeding, during which Dr. R. S. Caldecott (United States) considered the control of the mutation process.

The symposium illustrated the general realization that if the maximum benefit is to be obtained from common wheat which, with rice, is one of the world's most important food crop plants, the fullest understanding of its genetic architecture will be necessary. Already, however, the cytogenetic structure of wheat is better known than that of any other polyploid species, so that work on wheat is profoundly influencing general ideas on evolution by polyploidy and on the genetic functioning of polyploid organisms. The present position has resulted from combining the efforts of many workers over the years. Future progress will similarly be achieved by the accumulation of numerous individual contributions, and so will be most rapid and efficient if the people engaged are enabled to pool their ideas in the way which was possible at the first Wheat Genetics Symposium.

RALPH RILEY

INDIUM MONO-TELLURIDE

By H. C. WRIGHT and J. C. BRICE

Mullard Research Laboratories, Salfords, Surrey

SOME preliminary work has been carried out on the mono-telluride of indium. This revealed some anomalous properties of the compound, which is variously reported as semiconducting[1] and metallic[2]. The compound was prepared by direct fusion of stoichiometric amounts of the elements in sealed evacuated silica tubes. X-ray powder patterns of the compound showed only the lines reported by Schubert[3].

The resistivity and Hall coefficient were measured on four specimens at room temperature. They all showed a carrier density of 10^{18} holes cm.$^{-3}$ or more, and resistivities varying from 4×10^{-3} to 4×10^{-2} ohm cm. In an attempt to change the carrier type, specimens were prepared with 4 atomic per cent excess of each of the elements, respectively. The sign of the thermoelectric power of both these suggested *p*-type conduction.

The temperature coefficient of resistance was metallic from liquid nitrogen temperature to 440° K., at which point an anomaly was observed (Fig. 1). These measurements were made with increasing temperature. On cooling, the resistance at any given temperature was found to be dependent on time. This was investigated by holding a specimen at 463° K. for 16 hr. and cooling over a period of 15 min. to 358° K. The rate at which resistance at time t (R_t) approached its equilibrium value (R_∞) is shown in Fig. 2. It was found that measurements could be repeated provided adequate time for relaxation was allowed.

The thermal electromotive force was measured against copper, using an apparatus described elsewhere[4]. It varied from $1 \cdot 5 \times 10^2$ μV. °K.$^{-1}$ at 300° K. to $2 \cdot 2 \times 10^2$ μV. °K.$^{-1}$ at 580° K. without anomaly. A point-contact diode of the material showed no rectification for currents up to ± 100 m.amp.

Differential thermal analysis was carried out with a standard Gallenkamp apparatus using equal parts of tellurium and silica as a reference material. The results of two runs taken between 370° K. and 530° K. are shown in Fig. 3.

The thermal conductivity of the material was measured by holding one side of a thin disk at the ice point and the remote side in contact with a heated surface at temperatures varying from 290° K. to 490° K. The rate of heat transmission through the disk was deduced from measurements of the power necessary to maintain the heated surface at a given temperature θ with and without the disk in position. Each temperature was maintained for 15 min. These results are presented in Fig. 4 in the form of a graph of WL/A against θ, where W is the rate of heat transmission through the disk of thickness L and cross-sectional area A : the slope of this graph at any temperature yields the thermal con-

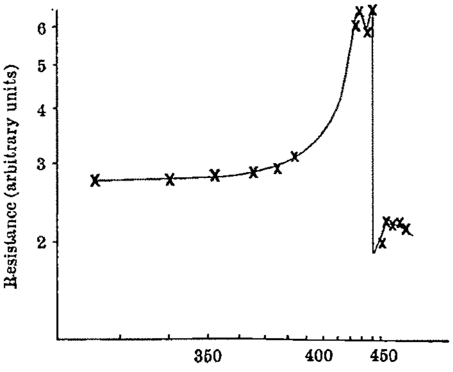

Fig. 1. Resistance versus temperature

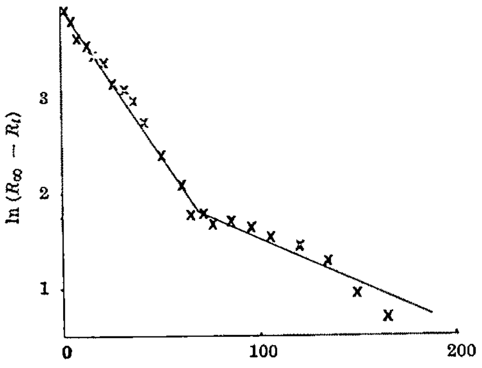

Fig. 2. Change of resistance with time

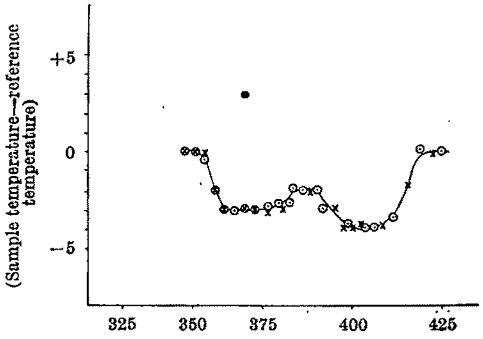

Fig. 3. Results of differential thermal analysis

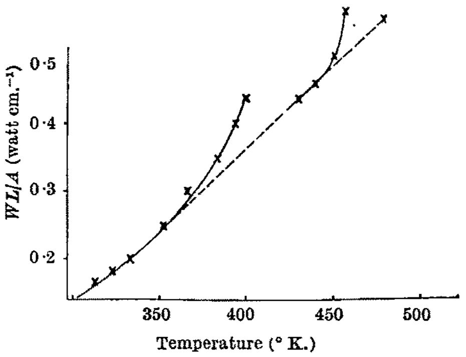

Fig. 4. Thermal conductivity

ductivity of the material at that temperature. This is about 2×10^{-3} joule $cm.^{-1}$ $°K.^{-1}$ except in the two regions between 363–393° K. and 448–473° K., where it is anomalously high.

An optical energy gap was sought by direct reflexion measurements but not found in the range 0·85–2·5μ. Powder reflexion measurements between 0·2 and 1μ yielded no evidence of an energy gap either. A practically constant photo-voltaic effect was seen to be present between 0·85 and 2·5μ. This could be attributed to the junction between the specimen and either of the *Leitsilber* (by Degussa, Frankfort) painted electrodes on it.

The double relaxation time apparent in Fig. 2, the differential thermal analysis result in Fig. 3 and the thermal conductivity graph, Fig. 4, all suggest that two-phase change mechanisms operate between room temperature and 450° K. The resistance/temperature graph shown in Fig. 1 indicates only one change, at 440° K.

Electrical measurements slightly favour a metallic model for the compound in view of the sign of the temperature coefficient of resistance, and the non-rectification of the point contact diode. The large value of the thermal electromotive force, the computed Wiedemann–Franz ratio of 2×10^{-7} $V.^2$ $°K.^{-1}$ at 300° K. and the large variation of resistivity are, however, more characteristic of a semiconductor than a metal.

Much of the preparative work was carried out by Mr. E. M. N. Baldwin and many of the measurements were made by Miss J. Schwarz.

DOES RHODOPSIN CONTAIN A TRACE METAL?

By ISAO FUKAMI, Prof. BERT L. VALLEE and Prof. GEORGE WALD

Biological Laboratories, Harvard University, Cambridge, Mass., and Biophysics Research Laboratory of the Peter Bent Brigham Hospital, Boston

ONE of the problems involved in the study of the visual pigments is the source of their colour. In rhodopsin, for example, the prosthetic group neo-*b* (11-*cis*) retinene has $\lambda_{\max.}$ in aqueous digitonin solution at about 384 mμ. On combination with the specific protein of the rods, scotopsin, to yield rhodopsin, $\lambda_{\max.}$ is displaced to about 500 mμ. On combination of the same prosthetic group with photopsin, the corresponding protein of the cones, $\lambda_{\max.}$ is displaced to about 562 mμ. In the attempt to understand how the combination with protein could induce such large spectral shifts, an analogy has been drawn with the antimony chloride test for retinene[1]. On mixing retinene with antimony chloride reagent, a photosensitive blue product is obtained with $\lambda_{\max.}$ about 655 mμ, shifting within 30–40 sec. to 664 mμ. Meunier and Vinet[2] had suggested that the source of the blue colour in the similar reaction of vitamin A is the passage of an electron from vitamin A to antimony chloride, to form a vitamin A cation; the greatly increased resonance associated with the electric charge introduced into the conjugated system of alternate single and double bonds causes the great enhancement of colour and large displacement of absorption toward longer wave-lengths.

These suggestions raised the question whether opsin might contain a metal ion which acts similarly upon the attachment of retinene.

Morton and his colleagues have made extensive studies of the occurrence of trace metals in eye tissues, including retinas. Copper and zinc were found primarily in the black tissues of the eye, associated apparently with melanin – protein complexes; only moderate amounts occurred in the retina[3]. In cattle, the retina is particularly rich in manganese, but the outer segments of the rods which contain the rhodopsin have less of this metal than the other retinal tissues[4].

The particular problem in the present instance is to determine whether rhodopsin (opsin) itself contains a trace metal, and for this, of course, it is necessary to remove all contaminating ions. The de-ionization of solutions with ion-exchange resins is now a well-known procedure. Ordinarily, such resins induce

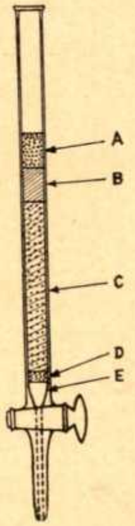

Fig. 1. Arrangement of mixed ion-exchange resins modified from Dintzis (ref. 5). The resins were mounted in a burette in the following order: (*A*) 2 ml. of 'IR-120' in the ammonium cycle form; (*B*) 2 ml. of 'IRA-400' in the acetate cycle form; (*C*) 10 ml. of a mixture of 14 volumes of 'IR-120' in the hydrogen cycle form and 36 volumes of 'IRA-400' in the hydroxyl cycle form; (*D*) about 0·2 ml. of 'IR-120' in the hydrogen cycle form; and (*E*) a plug of glass wool. Both resins employed were the standard 9–10 per cent cross-linkage, 20–50 mesh (Rohm and Haas)

sufficiently high alkalinities or acidities to denature proteins, but Dintzis[5] has devised a combination of resins, variously treated, which avoids this difficulty. Recently, Albrecht[6] used a column of such mixed-bed ion-exchange resins to remove ions from solutions of cattle rhodopsin, and found that this treatment, while removing inorganic ions and small-molecular peptides, does not alter the absorption spectrum of rhodopsin or its regenerability after bleaching.

In the present experiments the same procedure was used to prepare ion-free cattle rhodopsin. All operations were carried out in red light to avoid bleaching. Rhodopsin was prepared from the outer segments of cattle rods, separated from the remaining retinal tissues by differential centrifugation, and pre-extracted with aqueous buffer and petroleum ether, as previously described[7]. At a late step in preparation the buffer solution used to wash the rod residues was replaced by ion-free water to remove the bulk of the salts. The rhodopsin was then extracted with 2 per cent digitonin solution. Its purity was estimated optically through the ratio of extinctions at 400 and 500 mμ (E_{400}/E_{500}); the lower this index, the purer is the preparation. Pure cattle rhodopsin has E_{400}/E_{500} about 0·22. The concentration of rhodopsin was determined from its known[8] molar extinction coefficient at 500 mμ, namely, 40,600.

The design of the resin column is shown in Fig. 1. The column was held for at least one hour at 4° C., and then washed by running ion-free water through it at the same temperature. Since the cattle rhodopsin is dissolved in 2 per cent digitonin solution, this was the eluent used in the procedure. Ion-free digitonin solution was prepared initially by passing 2 per cent digitonin over the mixed bed of resins represented at *C* in Fig. 1. After this treatment the digitonin solution had an electrical conductivity less than $5 \cdot 0 \times 10^{-6}$ mho.

About 15 ml. of such ion-free 2 per cent digitonin was first run through the column at a rate of flow of 0·5 ml./min. Effluents were collected in 3-ml. aliquots. Usually the fourth fraction was set aside as the control digitonin solution for the metal analysis. At the moment when the last of the digitonin left the top of the column, 4 ml. of rhodopsin solution was pipetted on to the column. When this had entered the column, an additional 15 ml. of ion-free digitonin solution was introduced from a pipette and allowed to run through, always at a constant rate of flow. The effluent samples containing the rhodopsin were identified spectrophotometrically, and through the observation that they possess a slightly higher electrical conductivity than ion-free digitonin solution.

After a first preliminary trial, two further rhodopsin solutions were prepared and purified to the limits of these procedures. Their characteristics are shown in Table 1. The second of these solutions was less contaminated with extraneous material absorbing in the ultra-violet than the first, as shown by the lower E_{400}/E_{500} ratio; and it had also a lower specific conductivity. In both cases the *p*H of the de-ionated solutions was 5·2–5·3, close to the isoelectric point of cattle rhodopsin[9].

The metal analyses were performed at the Biophysics Research Laboratory of the Peter Bent Brigham Hospital in Boston, by methods of quantitative emission spectrography described elsewhere[10]. The samples were ashed at 450° C., and dissolved in 6 *N* hydrochloric acid. Spectral line emission was excited with a high-voltage copper spark; for this reason copper itself was not measured. The spectrograph was a 21-ft. Wadsworth mounting equipped with a grating with 15,000 lines/in. and having a reciprocal linear dispersion of 518 A./mm. Eastman No. 103–0 photographic plates were employed, and the spectral lines were measured and corrected for background emission with a microdensitometer (Jarrell-Ash). The procedure was calibrated with spectroscopically pure chemicals obtained from Johnson Matthey and Co., Ltd.

The results of these analyses are shown in Table 2. For each of them 2 ml. of the preparations described in Table 1 were used. Except for aluminium, small amounts of which apparently are carried into these

TABLE 1. PROPERTIES OF TWO RHODOPSIN SOLUTIONS PURIFIED BY PASSAGE THROUGH MIXED-BED ION-EXCHANGE COLUMNS

(1) Ratio of extinctions at 400 and 500 mμ, a measure of optical purity; (2) extinction at 500 mμ, and below it, in parenthesis, the molar concentration of rhodopsin; (3) electrical conductivity in reciprocal ohms; (4) ratio of electrical conductivity before and after de-ionization on the column; (5) *p*H of the final solution

	1 E_{400}/E_{500}	2 Extinction and (molar concentration)	3 Conductivity (mho)	4 Decrease of conductivity through de-ionization	5 *p*H
Rhodopsin (I)	0·36	1·375 ($3 \cdot 39 \times 10^{-5}$)	$9 \cdot 88 \times 10^{-6}$	1/14·8	5·25

Digitonin control	—	—	$5 \cdot 0 \times 10^{-6}$	1/2·85	6·3

Table 2. METAL ANALYSES OF RHODOPSIN SOLUTIONS DE-IONATED BY PASSAGE THROUGH A MIXED-BED ION-EXCHANGE COLUMN
In each case 2 ml. of rhodopsin solution was ashed and analysed. Results are expressed as μgm./ml. sample as measured, and in the summary rows the corresponding ion equivalents per litre are given for comparison with the concentration of rhodopsin in moles per litre stated

Sample	Zn	Ni	Cd	Fe	Mn	Cr	Ca	Al	Mg	Sr	Mo	Co	Ba	Pb
Rhodopsin (I) ($3\cdot39 \times 10^{-5}$ mol./l.)	0·8	0	0	0·9	0	0	0	0·3	0	0	0	0	0·02	0
Digitonin control	0·6	0	0	0·6	0	0	0	0	0	0	0	0	0·09	0
Net content (ion equiv./l.)	$3\cdot1 \times 10^{-6}$			$5\cdot5 \times 10^{-6}$				*						
Rhodopsin (II) ($4\cdot56 \times 10^{-5}$ mol./l.)	0	0	0	0	0	0	0·3	1·5	0	0	0	0	0·02	0
Digitonin control	0	0	0	0	0	0	0·19	0·05	0	0	0	0	0·01	0
Net content (ion equiv./l.)							$2\cdot5 \times 10^{-6}$	*					$7\cdot3 \times 10^{-8}$	

0, Not detected.

* The values for aluminium are probably spurious, this metal having entered with the use of alum during the preparation.

rhodopsin preparations through the use of alum to 'tan' the rod outer segments, no other metal ion measured proved to be present in concentrations approaching the molar concentration of rhodopsin. Zinc and iron, found in traces in preparation I, were not detectable at all in the purer preparation II. The latter contained a trace of calcium which did not appear in preparation I. A trace of barium appeared in preparation II, but did not seem at all significant, both because it was negligible in amount, and because in preparation I more barium was found in the control digitonin solution than in the rhodopsin. Copper, as indicated, was not measured because a copper spark was used to excite emission. Of the elements that were measured, it seems clear that none exists in cattle rhodopsin in significant amounts.

These experiments offer no evidence for the participation of a metal ion in the structure of rhodopsin. Probably, therefore, there is no need to invoke the action of a metal ion in attempting to account for the chromophoric properties of retinene in any of the known visual pigments. Another mechanism that has recently been proposed, based entirely on organic structures, appears more likely to account for these properties[11].

This investigation was supported in part by funds from the Rockefeller Foundation and the U.S. Office of Naval Research.

NEW VARIANT OF HUMAN FŒTAL HÆMOGLOBIN

SEVERAL variants of the normal adult hæmoglobin A have been recognized. Furthermore, recent reports[1,2] indicate the existence of variants of the normal human fœtal hæmoglobin F.

In a paper electrophoretic study of the hæmoglobin from newborn infants, one sample (the 140th of this survey), in addition to the usual pattern $F + A$, also contained a smaller component of less anodic mobility than F (Fig. 1*a*). Comparison with known hæmoglobin variants at *p*H 8·0–8·6 disclosed that this component is slower than hæmoglobin S and only slightly faster than E and A_2 (Fig. 1*b* and *c*). At *p*H 6·7 (phosphate buffer, $\Gamma/2$ 0·1) this fraction moved rather like S.

By agar electrophoresis[3] only two spots, corresponding to the positions of hæmoglobins F and A, were obtained. Since this technique is very adequate for the detection of small amounts of hæmoglobins S and C, such as might have been present at birth, the absence of an additional spot anodically to A further excludes the presence of either S or C.

So far hæmoglobin O is the only variant known to occupy a position intermediate between E (and A_2) and S at alkaline buffer[4]. Comparison of the component under study with O disclosed that both are of similar mobility (Fig. 1*d*). Hæmoglobin O, however, can also be demonstrated on agar, where it occupies a position anodically to A (personal communication from Dr. Lie-Injo, confirmed by our comparisons); this property of O distinguishes it from the fraction described here.

Starch electrophoresis at *p*H 8·6 resulted in a pattern similar to the one obtained on paper. Eluates of the isolated fractions were concentrated and sub-

(*a*) Sample 140, containing fraction X in addition to $A + F$; (*b*) above, artificial mixture containing A, F and S; below, sample 140; (*c*) above, sample 140; below, hæmoglobin $A + E$; (*d*) above, sample 140; below, hæmoglobin $A + O$

jected to electrophoresis again on paper; the slow fraction was very pure, containing only a small amount of *F*. Agar electrophoresis of this fraction revealed only one spot at the position of *F*; such a position of the isolated component can also serve to distinguish it from two other hæmoglobins, which on paper occupy neighbouring places: on one hand *D*, which does not separate[3] from *A*, and on the other A_2, which according to our observations also does not separate from *A* on agar.

The alkali denaturation rate of the isolated slow fraction was measured by a technique adapted from Jonxis and Visser[5]. The rate obtained was similar to that of hæmoglobin *F* from cord blood and to that of the fraction containing mainly *F* of the same electrophoretic separation of sample 140 (Fig. 2).

The ultra-violet spectrum of the fraction under study, following starch electrophoresis of hæmolysates appropriately prepared[6], was very similar to that obtained for hæmoglobin *F* as regards the tryptophan band (Fig. 3).

This sample of cord blood contained 18·3 per cent of the abnormal fraction. Over the ensuing fifteen weeks the abnormal fraction diminished progressively to 2·2 per cent; a parallel diminution of the total alkali-resistant pigment from an initial 60 per cent to 6 per cent was observed.

The newborn presented no clinical or hæmatological abnormality. Of the parents the father was unknown and only the mother was available for study: she was normal.

Our findings suggest that this is another variant of fœtal hæmoglobin: it is similar to hæmoglobin *F* as regards progressive disappearance within the first months postnatally, alkali denaturation-rate, ultra-violet spectrum, and mobility on agar, but definitely distinct from *F* on paper and starch electrophoresis. It is interesting to note that an increased resistance to alkali and an ultra-violet spectrum similar to that of *F* were reported for the fœtal variant 'Bart's'[2].

The possibility should be considered that this variant represents the early normal embryonic hæmoglobin, the existence of which has been suggested by other investigations[7-9]; should this be the case, it must be admitted that in the present instance the early embryonic variant persisted beyond birth. However, the embryonic hæmoglobin of Drescher and Künzer differed from *F* by a definitely faster denaturation-rate[7], while the hæmoglobin of Halbrecht and Klibanski, although slower than *F* on paper, could not be clearly separated from the latter in spite of a prolonged electrophoresis[9]. Furthermore, the mobility of the present fraction was obviously different when compared with hæmoglobin from a 15-week-old fœtus.

The tentative name 'Alexandra' is suggested for the fœtal hæmoglobin described here.

We are indebted to Dr. Lie-Injo Luan Eng, of Djakarta, for supplying samples of hæmoglobin *E* and *O*. We also wish to thank Dr. Gnafakis of the Department of Obstetrics and the staff of the Pædiatric section of the Alexandra Maternity Hospital for helpful collaboration. The Department of Therapeutics, University of Athens, placed at our disposal the spectrophotometer used in this study.

WHEREAS numerous variants of adult human hæmoglobin (*A*) have been described, there have been few descriptions of hæmoglobins which might be considered variants of the fœtal pigment (*F*)[1,2]. These were concerned with 'fast moving' hæmoglobins, which, on paper electrophoresis at alkaline *p*H, moved towards the anode faster than hæmoglobin *A*. The present report is concerned with a 'slow-moving' component seen in cord blood hæmoglobin collected in Singapore. Usually this pigment is present in very small amounts and cannot be detected with the naked eye, but has to be made visible by drying the paper after electrophoresis and staining it with a protein dye or with benzidine (pseudo-peroxidase reaction). Amounts visible without staining have, however, been found in several Chinese, three Malays, one European (English) and one Eurasian. One sample (Chinese cord blood 675), in which the proportion of this 'slow' component amounted to about 15 per cent of the total hæmoglobin, was suitable for further investigation. The infant had been delivered normally and its weight at birth was 7 lb. 13 oz. Both parents are healthy Chinese living in Singapore and neither of them shows any abnormality of the hæmoglobin on electrophoresis.

On paper electrophoresis at *p*H 8·6, one fraction was seen in the position of hæmoglobins $A + F$, and the other moved more slowly than hæmoglobins S or D, or faster than hæmoglobins E or A_2. On ion-exchange resin chromatography and agar electrophoresis, both using citrate buffer at *p*H 6·2 where A and F can easily be distinguished, the sample separated into two components. The major fraction occupied a position similar to that of hæmoglobin F, and the minor fraction one similar to that of hæmoglobin A_1. The two fractions were eluted, and on paper electrophoresis at *p*H 8·6 it was seen that the major fraction was composed of hæmoglobin F and the new hæmoglobin. Thus on paper electrophoresis at *p*H 8·6 the new hæmoglobin resembles hæmoglobin O, which by this technique migrates between S (or D) and E (or A_2), and on chromatography and agar electrophoresis at *p*H 6·2 it resembles hæmoglobin F and unlike O moves faster than A.

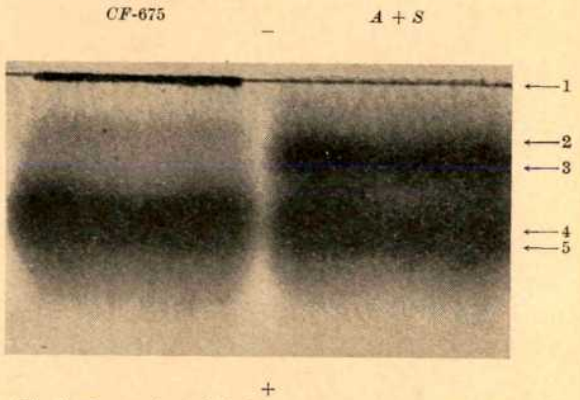

Fig. 1. Comparison of the hæmoglobin from Chinese cord blood *CF*-675 with a hæmoglobin $A + S$ control by paper electrophoresis at *p*H 8·6, hanging strip technique. The paper strip was dried and photographed unstained. (1) Line of application; (2) slow-moving component in *CF*-675; (3) hæmoglobin S; (4) hæmoglobin $F + A$ in *CF*-675; (5) hæmoglobin A

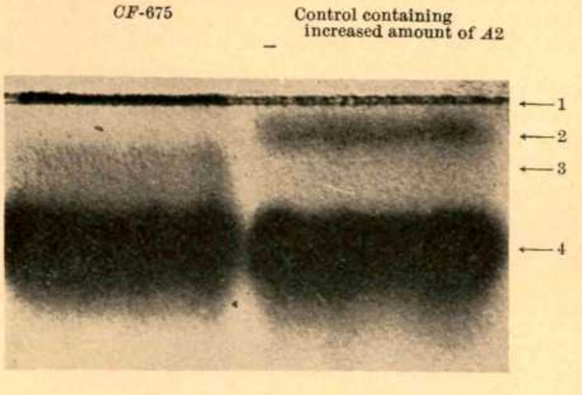

Fig. 2. Comparison of the hæmoglobin from Chinese cord blood *CF*-675 with a control containing hæmoglobins A_1 and F and an increased amount of hæmoglobin A_2. Technical details as for Fig. 1. (1) Line of application; (2) hæmoglobin A_2; (3) slow moving component in *CF*-675; (4) hæmoglobin A_1 (and F)

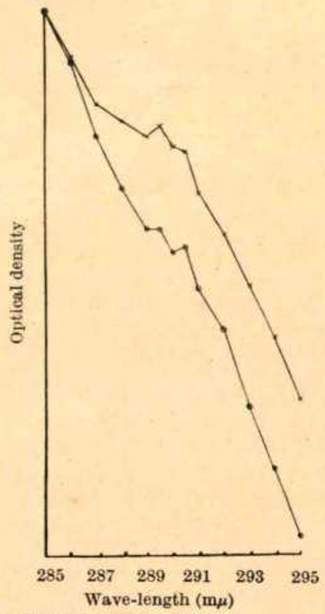

Fig. 3. Ultra-violet spectrum of the slow component isolated from Chinese cord blood *CF*-675 and of purified hæmoglobin from human cord blood containing 80 per cent F and 20 per cent A. ×—×, Cord blood control; ○—○, Chinese cord blood *CF*-675 slow component

It was unfortunate that the hæmoglobin solution had to be transmitted in the carbonomonoxy form and the alkali-denaturation properties of the isolated pigment could therefore not be determined. The ultra-violet spectrum was determined after elution from paper after electrophoresis. It showed a tryptophan fine-structure band of the fœtal hæmoglobin type.

We reported the observation of a slow-moving fœtal component to Dr. Ph. Fessas, who kindly informed us that he had observed a similar or perhaps identical abnormal fœtal hæmoglobin at the Alexandra Hospital in Athens which he proposed to call hæmoglobin 'Alexandra'. As it is very likely that the slow-moving hæmoglobins from cord blood seen in Athens and in Singapore are the same, we have thought it preferable for the time being to refrain from naming the new hæmoglobin described here.

Smoke Emission of Low-Temperature Chars

It has been accepted in the past that coals are effectively smokeless when they contain less than 20 per cent of volatile matter. Thus the approved smokeless fuels include low-volatile steam coals ranging in volatile content from 9·1 to 19·5 per cent and manufactured fuels of volatile content near or less than the lower limit of this range. Consequently, the assumption is sometimes made that, in order to be smokeless, coal products must have their volatile content reduced to less than 20 per cent.

This assumption is unjustified. Early work by Piersol[1] showed that devolatilization of certain American coals gave chars which were smokeless although their volatile contents exceeded 20 per cent. At the Coal Research Establishment a similar effect has been found for high-volatile British coals which were devolatilized by fluidized carbonization. Briquettes made from a char of 33 per cent volatile content emitted less smoke than a steam coal of 18 per cent volatile content, and when made from a char of about 23 per cent volatile content they were completely smokeless.

The smoke emission of a series of chars of different volatile contents and of coals covering a similar volatile range has been investigated. From both coals and chars, the smoke consisted mainly of tar-like pyrolysis products which had escaped complete combustion. The smoke emission decreased with decreasing volatile content, but was always less for a char than for a coal of the same volatile content. Nevertheless, as shown by Fig. 1, a common relationship for coals and chars was found between the smoke yield on combustion and the tar yield as measured by a Gray–King assay. It is concluded that the smoke emission of coals and chars is mainly determined by the yield of tar on carbonization. A char of 23 per cent volatile content is smokeless because its yield of tar is small. This is mainly due to the fact that during the preparation of the char, a considerable amount of tar has already been evolved from the parent coal.

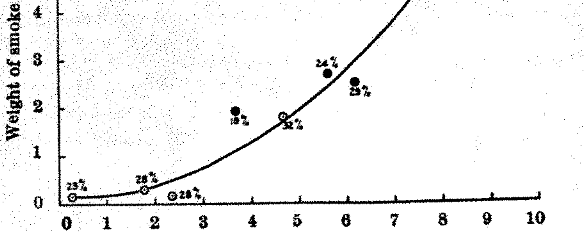

Fig. 1. Relation between weight of smoke and tar yield. Figures adjoining points are volatile matter contents (percentage d.a.f.). ●, Coals; ⊙, chars

Table 1. Yields of Products from the Carbonization of Cannock Wood Coal
(Percentages of dry coal)

Carbonizing conditions	Char	Tar	Liquor	Gas
Coal carbonized to 425° C.	87·7	6·7	3·8	1·4
Char recarbonized to 550° C.	77·8	1·8	4·0	4·0
Total yields from two-stage carbonization	77·8	8·5	7·8	5·4
Coal carbonized directly to 550° C.	76·8	9·8	7·1	6·2

A second factor, however, also contributes to the low yield of tar from a smokeless char. When a high-volatile coal was carbonized at 5 deg. C. per min. to 425° C. to give a smokeless char, the yield of tar was 6·7 per cent by weight. Carbonization of the coal under the same conditions but to 550° C. (a temperature sufficiently high for the maximum yield of tar under these carbonizing conditions) gave 9·8 per cent yield of tar. It might therefore be expected that the yield of tar obtained by carbonizing the smokeless char to 550° C. would equal the difference, namely, 3·1 per cent. The yield obtained (1·8 per cent) was significantly lower. Moreover, as shown in Table 1, the decrease in yield of tar was accompanied by a corresponding increase in the yield of char, the yields of liquor and gas not being significantly affected. These results show that when carbonization is carried out to a fixed upper temperature in two stages, some of the intermediate pyrolysis products, which would have been evolved as tar in a single-stage carbonization to that temperature, are converted into char. This effect is related to the observation of other workers[2-4] who, studying different aspects of coal pyrolysis, have also observed that when the upper temperature limit of carbonization is fixed, the yield of tar or coke depends on the carbonizing conditions. It is concluded that certain pyrolysis products of coal can either be evolved as tar or, if they are left in contact with the heated coal, undergo further reactions—possibly polymerization or condensation—to give a solid product.

Precipitation on a Dislocation

WE have recently made a study of the effect of heat treatment on silicon crystals containing up to 10^{17} aluminium atoms/c.c. After heating for several hours at a temperature of 1,250° C., transmission infra-red microscopy reveals the presence of a precipitated second phase within the crystals. In samples free of dislocations, these precipitates are needle-shaped and located at random sites, whereas in crystals with a dislocation density between 10^3 and 10^4 cm.$^{-2}$, the precipitation occurs almost entirely along the dislocation lines. These latter precipitates invariably appear as discrete particles strung out along the lines (Fig. 1).

A possible mechanism for the growth of the precipitates is suggested by the observation that these are discrete and lie along the dislocation lines, that is, the impurities migrate to the dislocation and then flow rapidly down the core to sites where precipitates have nucleated. Such a possibility has previously been suggested by Bilby[1] to explain the observed persistence of the $t^{2/3}$ law in some strain-aging and internal-friction experiments[2]. Bilby considers that, even in the later stages, the impurities migrate to the dislocation under predominantly drift forces. We consider, however, that the drift flow across any internal surface within the crystal is small compared with the diffusion flow. Such a proposition has recently been used to discuss the growth of an impurity atmosphere near a dislocation[3]. Since the boundary condition adopted in that treatment enforced zero net diffusion flow, the growth of the atmosphere was due entirely to the small drift perturbation.

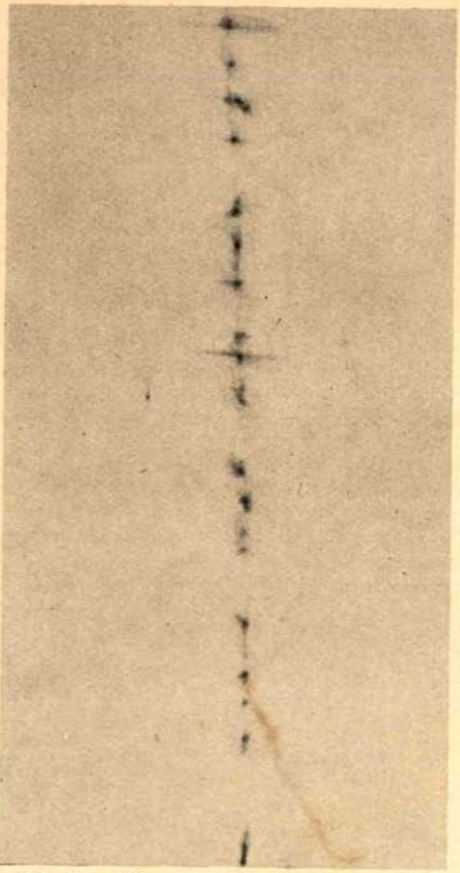

Fig. 1. Discrete particles along an isolated dislocation in aluminium-doped silicon after heating at 1,250° C. for 18 hr. (× 1,000)

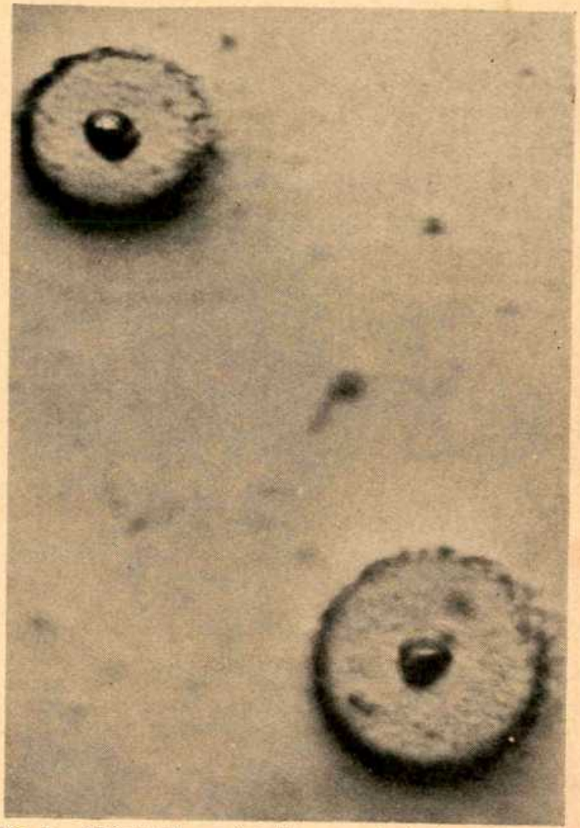

Fig. 2. Cylindrical p–n junction around single dislocations (× 2,200)

An essential feature of our model was that the impurities, in the core region, had extremely high mobility. The concept of high diffusion rates down the dislocation core at a later stage, when the impurity atmospheres have condensed locally to form discrete precipitates, is thus consistent with this model. Once such precipitates have nucleated, the relevant boundary condition is zero impurity concentration at the dislocation core. We assume here that the precipitates occupy only a small fraction of the total length of dislocation line. With this boundary condition, there will be a net diffusion flow across any internal surface, and hence to a first approximation drift flow may be neglected. The number of impurities reaching the core in time t with this boundary condition has been recently evaluated by F. S. Ham (private communication), although his reason for adopting this boundary condition is the opposite of ours, since he considers that impurity atoms are completely immobilized on reaching the centre of the dislocation. The number of atoms arriving at the dislocation in time t is a function of the dimensionless variable $m = Dt/r_0^2$, where D is the diffusion constant and r_0 is the radius of the dislocation core. The variation closely resembles $m^{2/3}$ for $0\cdot 1 \lesssim m \lesssim 20$. It is interesting to note that this variation is similar to that found in strain-aging experiments in steels containing small concentrations of carbon and nitrogen[2]. To obtain reasonable agreement, r_0 must be chosen in the range 20 A. $< r_0 <$ 60 A.; this range includes the value of r_0 obtained in our previous calculation for the growth of a Cottrell atmosphere[3].

If the precipitation process is governed primarily by drift flow, then one would expect an asymmetrical distribution of concentration around the dislocation core, due to the angular dependence of the potential field[4]. Our assumption, however, of the predominance of pure diffusion flow would lead to a radially symmetrical distribution. Silicon provides a unique opportunity to distinguish between these two possibilities. The flow of aluminium (a *p*-type impurity) to form such strings of precipitates as shown in Fig. 1 clearly depletes the region in the neighbourhood of each dislocation. Thus a *p–n* junction would be produced in this region if the crystal initially contained both phosphorus and aluminium, the concentration of the latter being slightly in excess, since no precipitation of phosphorus occurs. The trace of such a *p–n* junction is a line of equal aluminium concentration, and may be revealed as a step on the surface of the crystal by using the Dash etch[5]; at the same time, an etch pit is produced at the point of emergence of the dislocation line. Examples of this are shown in Fig. 2. The *p–n* junctions are seen to be circular and concentric about the etch pits, supporting our argument for radially symmetrical flow to the dislocations. A more stringent test would be to examine this contour after much shorter diffusion times; however, the technique is only feasible when the radius of the *p–n* junction is greater than the radius of the etch pit.

We wish to thank our colleagues in this Laboratory for support in carrying out this work. Thanks are also due to Dr. T. E. Allibone, director of the Research Laboratory, Associated Electrical Industries, and to the Admiralty, for permission to publish this communication.

Neutron Diffraction at a High-Flux Reactor

UP to the present, all neutron diffraction studies in Great Britain and practically all structural studies elsewhere have been carried out with neutron beams from reactors which have a peak flux of a few times 10^{12} neutrons per sq. cm. per sec.; for example, at Harwell the reactor Bepo has been used for this work. We have now made preliminary measurements with a spectrometer at the research reactor Dido, where a peak unperturbed flux of about 5×10^{13} neutrons per sq. cm. per sec. is available. We achieve in practice an increase of about twenty times the intensity of our neutron beam, and this increase is available for reducing proportionately the size of the sample for study. The advantage of this, for solid-state studies with neutron beams, can be seen in two ways.

For materials which are available only in polycrystalline or powder form it was previously necessary to use about 5 c.c. of material in order to attain reasonably large diffracted intensities and adequate angular resolution. The same result is now obtained with a volume of 0·3 c.c. This quantity of diamond powder, often used as a standard substance, has given peak intensities of 560 and 460 counts per min. for the (111) and (220) reflexions respectively on a background of 40 counts. Apart from the more obvious advantages of using small samples, there is an important prospective gain for magnetic materials: it will become a practical proposition to make samples with the iron isotope, iron-57, which has a nuclear scattering amplitude less than a quarter of that of ordinary iron and which is correspondingly less troublesome when distinguishing between the contributions from nuclear and magnetic scattering.

For single crystal investigations, a reduction in size by twenty times enormously increases the range of materials which can be obtained in crystals of sufficient size to be studied. Over the past few years structural studies have been made at Harwell using single crystals of many chemical compounds. The average size of crystal used has been 160 c. mm.; thus this now becomes about 8 c. mm., or a fragment with an edge of about 2 mm. each way. We quote as an example a result for potassium bromide which serves as a standard substance; a cleaved block with a volume of 5 c. mm. gave a peak count of 7,000 neutrons per min. for the (200) reflexion. As well as widening the range of materials which can be studied as single crystals, reduction of size brings the important additional advantages that corrections for secondary extinction will be much less significant, and crystal preparation using selected isotopes, for application of the isomorphous replacement method of structural analysis, will become practicable.

A description of the spectrometer, with an account of the problems posed by the higher flux, will be published elsewhere.

Tensile Strength of Asbestos

ASBESTOS is the generic name for those silicate minerals which cleave naturally into fibres, the three important species being chrysotile (white asbestos), crocidolite (blue asbestos) and amosite. This unique mineral structure lends itself better to measurements of tensile strength than do the more common minerals with isotropic or platy structures, which are extremely difficult to prepare in the form of adequate tensile specimens, although measurements on mica have been reported[1].

Very high values may be predicted for tensile strengths of silicates, from consideration both of the strengths of the stable silicon–oxygen chains or sheets which characterize these minerals, and of the cohesive pressures which exist in solids, and which must be equalized in order to break a specimen. An explanation for the discrepancy, which exists between the estimated tensile strengths of solids and the highest values usually obtained in practice, was given by Griffiths[2,3], who said in effect that the high strengths calculated were correct and that the tensile measurements were wrong. The tensile strength of asbestos has been measured by Syromjatnikoff[4] and by Badollet[5], who have reported various values, but none exceeding 330,000 lb./in.^{2}, which is a high value for a tensile strength (steel piano wire is usually quoted as having a strength of 350,000 lb./in.^{2}), but is only a fraction of the value to be expected.

We have carried out a large number of tensile measurements (including modulus determinations), on asbestos of different types and have found that results may be obtained which are much higher than any yet reported. By taking high-speed photographs during a measurement, we have also been able to demonstrate the type of failure which occurs when asbestos fibres break. Our initial work indicated that, in order to obtain accurate results, the cross-sectional area of the fibres should not exceed 10^{-5} cm.^{2}, this being calculated from the specific gravity, length and weight of the specimens determined on a microbalance with a sensitivity of 1 μgm. The samples were mounted on a slip of paper on two spots of 'Seccotine' and these covered with small squares of paper. In this way, a good grip for the jaws of the tensometer was provided, and there was no tendency for the fibres to slip through the glue. The paper was carefully cut through just before the stress was applied. The tensometer consisted of a modified 'Chainomatic' balance: the strain was determined by observing the pointer with a microscope.

Our investigation consisted of making a series of determinations of tensile strength for various lengths of fibre. Average results, as well as a maximum strength obtained at each length, are shown on Table 1. Each average strength reported is the mean of not less than 25 results, it being found that a larger number of tests did not appreciably alter the progressive average. Tests carried out on the same samples, over a period of two years, gave repeatable results to within a few per cent.

Table 1. TENSILE STRENGTH

Sample	Length of sample (cm.)	Ultimate tensile strength (10^3 lb./in.^{2})		Coefficient of variation (per cent)
		Average	Maximum measured value	
Amosite (Transvaal)	3·5	148	247	34·6
	2·5	146	248	35·0
	1·7	172	269	29·2
	1·0	192	283	32·5
	0·5	203	287	24·7
Crocidolite (Cape Province)	3·5	469	740	29·4
	2·5	470	735	31·3
	1·0	540	815	23·0
	0·5	585	870	24·5
	0·2	605	876	20·3
Chrysotile (Arizona)	3·5	186	314	34·8
	2·2	208	346	34·9
	1·5	236	425	40·0
	1·0	312	470	29·9
	0·5	309	596	34·7
	0·2	320	820	56·8
Chrysotile (Thetford, Canada)	2·5	281	604	34·5
	1·5	321	670	41·0
	1·0	355	704	41·1
	0·5	414	789	33·4
	0·2	436	824	31·3

Table 2. YOUNG'S MODULUS

Sample	Length of sample (cm.)	Young's modulus (10^6 lb./in.^{2})	Coefficient of variation (per cent)
Amosite (Transvaal)	3·5	23·6	8·7
Crocidolite (Cape Province)	3·5	27·1	6·8
Chrysotile (Arizona)	3·5	23·2	9·9
Chrysotile (Thetford, Canada)	2·5	23·1	10·6

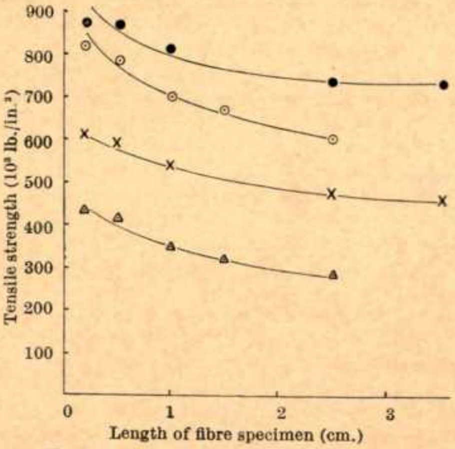

Fig. 1. The observed tensile strengths of Canadian chrysotile (⊙, maximum; Δ, mean) and of South African crocidolite (●, maximum; ×, mean) plotted against length of fibre specimen

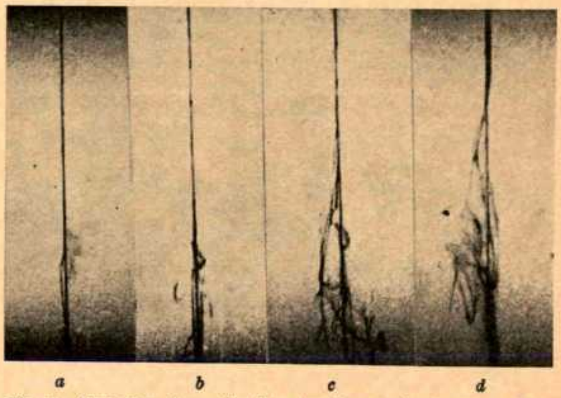

Fig. 2. Canadian chrysotile fibre breaking under tension. The intervals between each of the four exposures are 16·5, 32 and 44 thousandths of one second, respectively

Relatively long fibres were used to obtain values of Young's modulus, which are given in Table 2. For amosite and crocidolite asbestos, the plots of load versus extension were straight lines up to the breaking point. For chrysotile asbestos, plastic deformation occurred when the tensile stress exceeded about 80 per cent of the breaking load; the straight portions of the curves were used for calculating Young's modulus.

The tensile determinations show that in the most favourable circumstances, and using very short fibres, tensile strengths of approximately 900,000 lb./in.^{2} may be obtained, approaching the value of 1,500,000 lb./in.^{2}, which Orowan has suggested[6] for solids of this type (Fig. 1). The photographs (Fig. 2) demonstrate the mechanism of failure during the tests, which is comparable with that of mica, reported by Orowan[7]. Amosite gave a more brittle and sudden fracture which could not be resolved on our photographs.

Thus it appears that failure usually begins at a surface flaw but that the strain is relieved by rupture of the relatively weak interfibrillar bonds, thus producing broken fibres at that point, but exposing the surfaces of fresh fibres which may begin to fail at quite a different place. The possibility of failure beginning at surface flaws is clearly reduced as the length of the specimen is decreased, thus enabling higher tensile strengths to be measured on shorter specimens.

We are grateful to Prof. E. Orowan, of the Massachusetts Institute of Technology, for helpful comments, and to the directors of the Cape Asbestos Co., Ltd., for permission to publish these results.

Simulation of Lunar Craters: a Blow-hole Theory

Recent reports of volcanic activity on the Moon[1] have stimulated us to repeat an accidental observation made many years ago by one of us (A. G. G.). During rapid evacuation of a quantity of magnesium carbonate in a flask, a number of blow-holes appeared as the occluded gas escaped, leaving a pattern of rings, some with central 'pimples', closely resembling lunar craters. In the present work, we have repeated this experiment (Fig. 1). We have also put a quantity of dry powder (sand, salt, magnesium oxide or magnesium carbonate) in a 5-l. flask, which was continuously evacuated; a small flow of air was admitted at the bottom of the flask by a small hole. Various forms of blow-hole were observed. In many cases, a marked ring, with steep inner edge and less steep outer edge, was formed by the fountain of small particles; sometimes, when the air was cut off, a small pimple remained at the centre of the fountain as it collapsed (Fig. 2). The form of the 'crater' varied rather with type of powder, especially its angle of slip, and the depth, and with the rate of flow of gas.

It is known that terrestrial volcanoes may emit large quantities of dust and ash (cf. the fate of Pompeii), but the presence of an atmosphere interferes with the free fall of the particles. On the Moon, with no atmosphere, lower gravity, and probably a dry, 'sandy' surface, formation of the craters, with or without a central peak as the blow-out peters out, seems possible. It should be noted that the escape of gas trapped beneath the Moon's loose 'sandy' surface, with the formation of this type of blow-hole crater, would not necessarily require the high subsurface temperatures usually associated with volcanic activity.

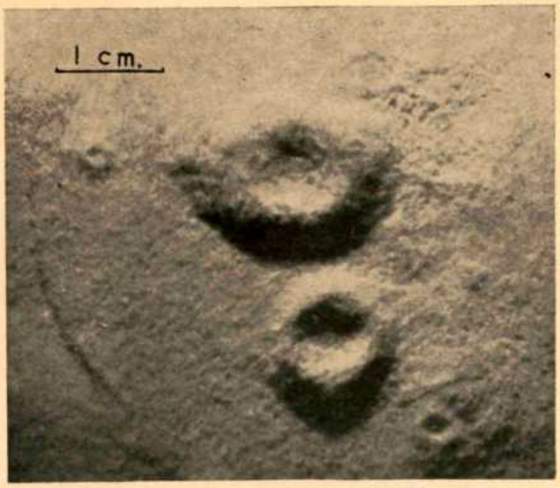

Fig. 1

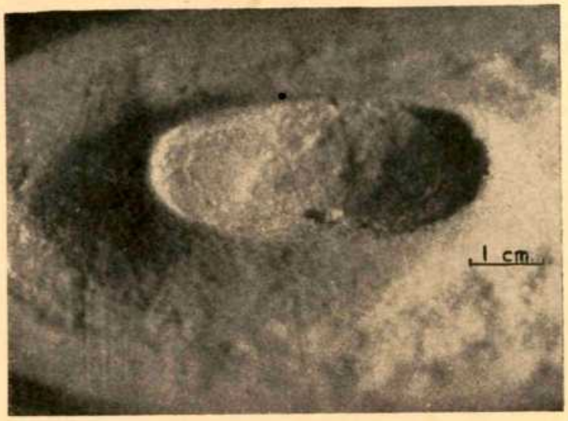

Fig. 2

The meteoric theory of craters seems unable easily to account for the circular, rather than oval, shape made by the non-vertical fall of a meteorite, or for the very smooth surface of the area within the ring. In our experiments, the region within the craters was usually fairly flat, although the formation of a fluidized bed may account for this, and such a condition seems unlikely on the scale of the lunar surface.

Recent unconfirmed reports[1] of C_2 emission bands near the crater Alphonsus may not necessarily indicate that the gas has a very high initial temperature. It has recently been shown[2] that shock-wave excitation of CO, CO_2 or CH_4 produces C_2 Swan emission. Shock-waves can be produced by a sudden release of pressure, as in the bursting-diaphragm shock tube.

While these theories are speculative, it seems that the possibility of lunar craters being caused by fountains of dust blown out by trapped gas should be considered.

Microwave Dielectric Properties of Indian Shellac in the 8-mm. Range

Shellac is produced in India after refinement from natural seedlac which contains more than 88 per cent of lac and 4·5 per cent of wax, the remainder being made up of colouring matter, gluten and moisture. Various grades of commercial shellac contain varying percentages of soluble impurities, wax, rosin and moisture. For microwave work a very high degree of purity is needed in dielectric samples. The three grades of shellac, 'Blonde', 'Crown' and 'Granta', manufactured by Angelo Bros., are free from rosin and orpiment and contain only 0·5–0·1 per cent of the insoluble impurities.

They are at present the only samples of the highest degree of purity available and have therefore been used for dielectric measurements in the 8-mm. band. Measurements have also been taken in two other electrical grades used for micanite. The dielectric loss in shellac, grade 'Blonde', is found to be the lowest in the 8-mm. band, and for this grade measurements of loss have also been carried out over a very wide band of radio frequencies.

The microwave dielectric properties of several grades of shellac at radio-frequencies have been reported[1] and the variation of the dielectric loss with temperature has also been studied[2] in three grades of shellac of high purity in the 3-cm. band. The loss factor in the case of shellac lies in the medium range so that the standing-wave technique of Von Hippel[3] is found to be most suitable and accurate. A suitable test bench with a *VX* 357 klystron oscillator, an attenuator and a Hilger standing-wave indicator Type *W*870 with frequency meter and crystal detector were used. The oscillator could operate continuously in the range 8·35–9·16 mm. with a maximum power output of 19·5 MW. The unit was situated in an air-conditioned laboratory and additional air cooling was provided by an external assembly of air blowers, to keep frequency-drift to a minimum. A dielectric cell with a movable shorting plunger was made in the laboratory. The square law response of the crystal, depth of probe penetration and standing wave ratio with the shorting plunger were adjusted in accordance with the standard methods[4].

Wave-guide samples of shellac were made by softening the material, obtained in the form of flakes of high purity, and then moulding it in a die under pressure. The die was kept warm, to prevent entrapping of air bubbles, and only samples free from them were used for these experiments. At least three samples of each grade of shellac of varying thicknesses between $\lambda_d/4$ and $5\lambda_d/4$ were used for measurements of loss, where λ_d is the wave-length in the dielectric. All samples were first dried in an electric oven and then left in a desiccator for 45 hr.: it was found that moisture can be eliminated by this method without detriment to the sample.

The complex permittivity $\chi = \chi' - j\chi''$ has been determined at room temperature (25° ± 1° C.) at 35·65 Gc./s. ($\lambda_0 = 8{\cdot}412$ mm.) and the results are shown in Table 1. χ'' is represented in terms of the tangent of the loss angle, $\tan\delta = \chi''/\chi'$. A correction was also applied to the dielectric constant for clearance errors[5].

Dewaxed 'Blonde' grade of Indian shellac shows the lowest loss in the 8-mm. band. This particularly pure grade is made by a solvent process using cold alcohol, in which the wax is soluble. The measurements of dielectric loss in this grade were carried out over a wide frequency band from 10 kc./s. to 35 Gc./s. to find the peak of the dielectric loss. The *S*-band measurements were made on a shorted coaxial line[6] through the courtesy of Shri Krishnaji in the Department of Physics in the University of Allahabad. The tan δ – log f curve for this grade is shown in Fig. 1.

Table 1. DIELECTRIC CONSTANT AND LOSS OF INDIAN SHELLAC IN THE 8-MM. BAND

Grade of shellac	Insoluble impurities	Wax (per cent)	ε' at 25° C.	tan δ 25° C.
'Blonde'	0·1	Nil	2·761	0·0082
'Crown'	0·5	4·5	2·831	0·0379
XL	0·5	4·5	2·790	0·0310
'*C* Pure'	0·5	2·5	2·790	0·0661
'Granta'	0·5	3·0	2·780	0·0751

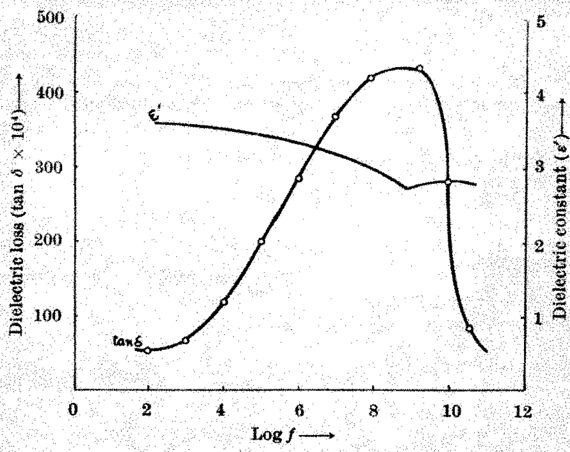

Fig. 1. Tan δ – log f curve of 'Blonde' grade shellac (0·1 per cent)

CHEMISTRY

Explosion of Transition Metal Co-ordination Compounds

IN a recent discussion on the initiation and growth of explosion in solids, Eggert[1] and McAuslan[2] reported on the initiation of explosions by light. Evidence was presented for the photochemical and/or photothermic effects in various nitrides, azides, acetylides and perchlorates.

During an investigation of the photochemical reaction of some transition metal complexes[3], the compounds $[Co(en)_3]_2(S_2O_8)_3$ and $[Cr(en)_3]_2(S_2O_8)_3$ were prepared as part of a programme to discover possible photosensitive systems among the solid co-ordination compounds of the transition elements. Quite accidentally, it was observed that the chromium compound produced an explosion, accompanied by the formation of a copious ash, when ignited by a flame. A systematic examination of this phenomenon showed that the explosion could also be initiated by exposing the compounds to ultra-violet radiation (3650 A.) followed by heating. The chromium compound exploded at 115° C. and the cobalt compound at 120° C.

While attempting to deduce the mechanism of the photosensitivity of these compounds brought about by ultra-violet radiation and heat, a severe explosion occurred as the chromium compound was being irradiated, and perhaps overheated, in a Vycor tube attached to the mass spectrometer. Further investigation showed that the controlled thermal decomposition following ultra-violet radiation resulted in the oxidation of the ligand with the evolution of nitrogen, carbon dioxide and water vapour.

This work was done at the University of Connecticut, Storrs, Connecticut.

Sealing of Aluminium Oxide Anodic Films

THE formation of boehmite on the surface of anodized aluminium by immersion in boiling water has been investigated by Hart[1]. In particular, studying ammonium borate anodic films on aluminium, he found by electron diffraction that the pseudo-amorphous structure of the surface layer was converted to boehmite, but that this change did not occur when the detached film was immersed in boiling water. Hart therefore suggested that the mechanism of the process was an outward movement of aluminium ions from the metal, passing through the oxide layer, and combining with hydroxyl ions to form boehmite in the pores of the existing oxide layer and on the outer surface.

Similar experimental results were also reported by Kerr[2], again after an electron-diffraction study of ammonium borate anodized films, when it was concluded that boehmite was formed only in the presence of metallic aluminium. Spooner[3], however, making an electron-diffraction study of sulphuric acid anodic coatings, found that conversion of the aluminium oxide layer to boehmite occurred in films attached to, and detached from, their aluminium bases, which confirmed that in this case the process was one of hydration of the existing oxide and did not require the presence of metallic aluminium.

It may therefore be of interest to report that working with boric acid anodic coatings we also found that conversion to boehmite occurs in films, detached from their aluminium bases, when sealed in boiling water.

Aluminium foil (99·99 per cent) of 0·012 mm. thickness was anodized at 550 V. in boric acid solution. After sealing by immersion in boiling water, the anodic film was stripped from the metal using saturated mercuric chloride solution and washed in distilled water. The resulting film was too thick to allow an electron diffraction transmission pattern to be obtained; but it was found that an outer layer, ~100 A. in thickness, could be obtained by evaporating a thin coating of aluminium on to the sealed film while still attached to the foil, and freeing this with a chromic–phosphoric acid solution[4]. An electron diffraction transmission pattern of this exceedingly thin aluminium-supported layer showed the presence of boehmite, the reflexions being compared and found to be in good agreement with published results[5].

An X-ray powder diffraction pattern of the whole film as separated by mercuric chloride, which was carefully wrapped on to a glass fibre, showed a predominantly γ-alumina composition with evidence of only a small amount of boehmite present. In a further study the film was removed from an anodized but unsealed foil, using the mercuric chloride technique, and boiled in distilled water for 20 min. An X-ray powder specimen was prepared as before, and the resultant diffraction pattern again showed the presence of boehmite and γ-alumina. In this case, however, a study of the relative intensities of the X-ray reflexions showed that an appreciable amount of γ-alumina had been converted to boehmite. This suggested that the greater surface area of the detached film had contributed significantly to the extent of hydration.

These results show that water-sealing of boric acid anodic films is a hydration process and occurs independently of the presence of metallic aluminium.

Electrode Potentials and Compound Formation in the Palladium–Platinum–Hydrogen System

ELECTRODE potentials and electrical resistances of palladium wires alloyed with 5, 10, 20 and 25 per cent platinum have been measured while they absorbed hydrogen (dissolved under a pressure of 1 atm.) from aqueous solutions of 2 *N* sulphuric acid. Apparatus and techniques were similar to those previously employed[1]. The wires were 0·027 cm. in diameter and were prepared by directly alloying the metals. The measurements reported were made on 15-cm. lengths of wire in the cold-drawn condition, which were preactivated by discharging oxygen at their surfaces by electrolysis[2,3]. Potentials differing from zero were positive with respect to a platinum hydrogen electrode in the same solution.

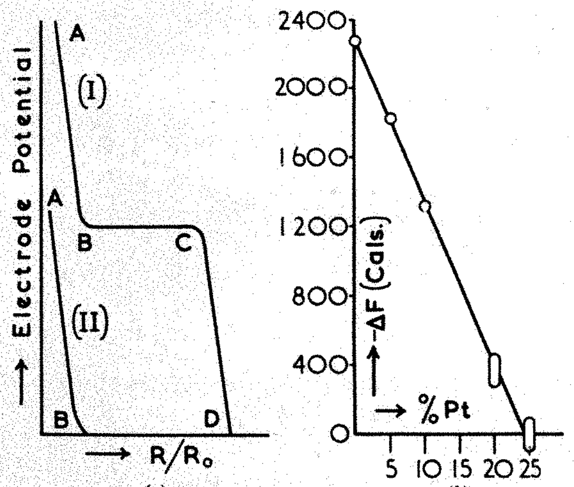
Selected experiments using the method of vacuum outgassing[1,2] indicated that the relative resistance (R/R_0) of the alloys was proportional to the hydrogen content, as has been established in detail for the palladium–hydrogen system[4]. Plots of R/R_0 against electrode potential for the alloys with 5, 10 and 20 per cent platinum revealed that they behaved[1] like palladium, showing the general relationship illustrated by I in Fig. 1*a*, although with increasing platinum content the step *BC* showed increasing departure from the horizontal with respect to the R/R_0 axis. The behaviour of the 25 per cent platinum alloy is shown by II in Fig. 1*a*. As was found for the palladium–hydrogen system, the equilibrium potential (*D* in Fig. 1*a*) is zero with respect to the platinum–hydrogen electrode.

The electrode potentials can be related to the change in free energy $\Delta \overline{F}$ for the reaction :

$$x\text{H} : y\text{Pt} : z\text{Pd} + \tfrac{1}{2}\text{H}_2 \rightleftharpoons (x+1)\text{H} : y\text{Pt} : z\text{Pd}$$

where x, y, and z represent numbers of atoms. Using the relation $\Delta F = -n\mathfrak{F}E$ and the experimental value of E, namely, 46·8 ± 0·5 mV., found for point B (Fig. 1*a*) in the palladium–hydrogen system at 30° C., ΔF for the formation of an idealized compound $\text{PdH}_{0\cdot5}$ is − 2,158 ± 24 cal./mole of hydrogen, between the limits PdH_r and $\text{PdH}_{r+0\cdot5}$, where PdH_r represents the composition at B (that is, the maximum solid solubility of hydrogen in palladium). This compares with $\Delta F = -2{,}306 \pm 12$ cal./mole of hydrogen which has recently been determined from gas-phase isothermal measurements[5]. The change in free energy associated with the formation of non-stoichiometric palladium–platinum–hydrogen compounds is also identified with the electrode potential represented by B (Fig. 1*a*) for each palladium–platinum alloy. (The definition of this point was subject to an uncertainty of ± 2 mV. in the case of the 20 and 25 per cent platinum alloys.) Fig. 1*b* shows these free energies of formation per mole of hydrogen, at 25° C., plotted against the platinum content of the alloys.

It has been suggested from previous evidence that a two-phase region analogous to that of the palladium–hydrogen system would not be formed by the absorption of hydrogen in palladium–platinum alloys with more than 5 per cent platinum. However, it is indicated by Fig. 1*b* that a two-phase region may occur in palladium–platinum alloys with less than 25 ± 2 per cent platinum.



(*a*) (*b*)

Fig. 1

Hydrogen dissolved in alloys with more than 25 ± 2 per cent platinum should be present only as a primary solid solution and appreciable solubility of hydrogen has been reported in palladium–platinum alloys containing 25–35 per cent platinum[6,7]. The gross dimensional changes of palladium foils which occur when they are repeatedly saturated with hydrogen[8] are possibly associated with the formation and collapse of the non-stoichiometric β-phase palladium hydride. Palladium–platinum alloys containing about 30 per cent platinum may therefore have advantages over pure palladium as diffusion membranes for hydrogen.

Acknowledgment is due to the Mond Nickel Co., Ltd., for providing the palladium–platinum alloys used in this investigation.

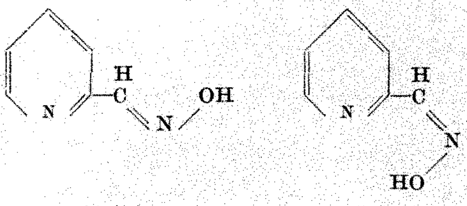
Ferrous and Ferric Complexes with Pyridine 2-Aldoxime

PYRIDINE 2-ALDOXIME forms well-defined coloured complexes with ferrous and with ferric ions in aqueous solution. The ferrous complex is violet-red in alkaline solution (with an absorption maximum at 530 mμ), reddish-orange in slightly acidic solution (with a maximum at 515 mμ), and golden-yellow below *p*H 3 (with a maximum at 475 mμ). The ferric complex is reddish-brown in alkaline, neutral and slightly acidic solution (with no absorption maxima in the visible), and yellow in more acidic solution. All the colour changes are reversible.

If this compound had the *syn* configuration (see Fig. 1), then these colour changes are most probably the result of ionization of the OH group. On the other hand, if the molecules are in the *anti* form, then the iron atom in the complex could only be bonded to nitrogen and oxygen, as can easily be verified by examination of atomic models. In the latter case the colour changes will have to be attributed to ionization on the basic unbonded nitrogen of the oxime.



(*syn*) (*anti*)

Fig. 1

Recently, Krause and Busch[1] prepared some nickel (II) complexes of this ligand. Drawing the analogy between their system and the corresponding ones with α-α′-dipyridyl and with dimethylglyoxime, they assumed that the nickel atom was bonded to two nitrogen atoms in the nickel complexes of pyridine 2-aldoxime. It would seem likely that the ferrous and ferric complexes of pyridine 2-aldoxime also involve bonding of the metal atom to two nitrogen atoms. This view is supported by the following

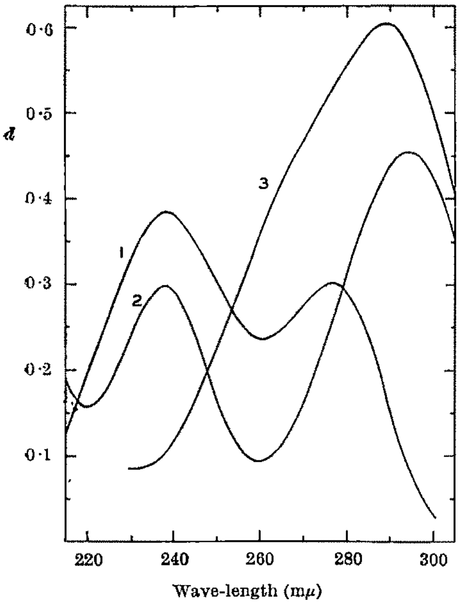


Fig. 2. Absorption spectra of $4 \cdot 0 \times 10^{-5}$ *M* pyridine 2-aldoxime showing three distinct and reversible species: (1) *PA*OH in water, absorption maxima at 238 and 277 mμ; (2) H*PA*OH at *p*H 2, maxima at 238 and 294 mμ; (3) PAO^- at *p*H 12, maximum at 289 mμ. Curves 1 and 2 have isosbestics at 218 and 279 mμ, and relate to the ionization with $pK \simeq 3$. Curves 1 and 3 have an isosbestic at 253 mμ, and relate to the ionization with $pK \simeq 10$.

evidence: (1) a number of ferrous complexes with oximes, where bonding to two nitrogen atoms has been established, have similar colours[2,3]; (2) structures of the iron(II) - pyridine 2-aldoxime complex made with Courtauld atomic models show that there is considerably less strain in the molecule when the iron is bonded to the *syn* form; (3) the infra-red spectrum of pyridine 2-aldoxime in chloroform shows a sharp band at 2·77μ which is characteristic of a free OH group; this favours the *syn* configuration rather than the *anti*, since in the latter structure the OH would most probably be involved in intramolecular hydrogen bonding with the pyridine nitrogen atom.

Pyridine 2-aldoxime shows two series of reversible spectral changes (Fig. 2) corresponding to two acid ionizations, one with $pK \simeq 3 \cdot 2$ at 25°, which is probably associated with the pyridine nitrogen, and the other with $pK \simeq 10 \cdot 2$, which is probably the ionization of the oxime OH. The normal acid *pK* value for pyridine nitrogen is 5·3, shifting to 5·8–6·0 in some pyridine-2-derivatives[4]; and for oxime OH the *pK* is[5] 12·5–13·0; in the present case conjugation could account for the increased acid strength of both groups.

Using the method of continuous variation, the composition of the ferrous complex was found to be 3 moles of ligand to 1 mole ferrous ion. This result was confirmed by measurements of changes of hydrogen ion concentrations accompanying the formation of the complex at different *p*H values, as well as by the constancy of the equilibrium constant for the formation of the complex calculated on this basis. At 25° these values are of the order of 10^{14} at *p*H 6, 10^{11} at *p*H 5, and 10^{8} at *p*H 4.

In order to account for the reversible colour changes, as well as the marked changes in the observed equilibrium constant with *p*H, we propose the following set of equilibria:

$$\begin{array}{lll}
Fe^{2+} + 3\,PAOH & \rightleftharpoons Fe(PAOH)_3{}^{2+} & (K) \\
Fe(PAOH)_3{}^{2+} & \rightleftharpoons Fe(PAO)_3H_2{}^{+} + H^+ & (K_1) \\
Fe(PAO)_3H_2{}^{+} & \rightleftharpoons Fe(PAO)_3H^0 + H^+ & (K_2) \\
Fe(PAO)_3H^0 & \rightleftharpoons Fe(PAO)_3{}^{-1} + H^+ & (K_3)
\end{array}$$

A preliminary spectrophotometric study of these equilibria indicated that $pK_3 \simeq 7 \cdot 0$ and $pK_2 \simeq 3$. It was not possible to determine pK_1 since the complex dissociates in more acidic solutions. However, the charges on these ions were substantiated by their behaviour on paper electrophoresis, and by measurements of changes of hydrogen ion concentration accompanying the formation reaction (in unbuffered solutions).

The corresponding ferric complex of pyridine 2-aldoxime is reddish-brown over a wide *p*H range. Only one reversible colour change, to orange, could be observed, corresponding to $pK \simeq 2$. This most probably corresponds to pK_3 of the ferrous complex, the other ionizations being those of strong conjugate acids. The shift in pK_3 from the ferrous to the ferric complex is of the same order of magnitude as that observed for the first ionization of hydrated ferrous and ferirc ions[6,7]. On the other hand, the shift of *pK* for the OH group in free pyridine 2-aldoxime and its ferrous complex, respectively, is unexpectedly large, considering that the types of charge are the same in both the ionization of the free ligand and the third ionization of the ferrous complex. The shift, which is clearly the result of co-ordination of the ligand to the metal atom, shows the extent to which co-ordination can influence adjacent ionizable groups. In this case, the interaction between the metal and the ionizing group is substantially increased through conjugation of the type shown in Fig. 3; in other cases, different types of interaction would be expected to produce different shifts in *pK* values.

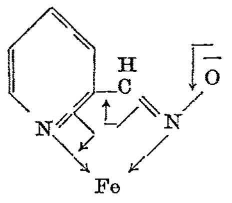

Fig. 3

These results may well be of significance in the interpretation of data obtained for all systems where there are linked effects between the metal ion and the ionizing side-groups of the ligand, such as occurs in hæmoproteins. Studies of this nature help in placing limits on the magnitudes of *pK* changes for ionizing groups which might be expected on account of the difference between their structural environment in the free ligand—where there are no linked effects—and in co-ordination complexes, where specific interaction with the metal ion can occur.

A more detailed study of the kinetics and thermodynamics of this system is being carried out. It is also hoped to extend this work to include systems incorporating other ionizable side-groups as well as other types of interaction.

We wish to thank Profs. A. Day and P. George for their co-operation. This work has been carried out as part of a programme supported by grants from the United States Public Health Service

Mechanism of Formation of Anthocyanidins from Leucoanthocyani(di)ns

Based mainly on suggestions made earlier by Robinson and Robinson[1] for their hypothetical *leuco*anthocyanin (flavan-2.3.4-triol), the conversion of flavan-3.4-diols (I) into anthocyanidins by similar mechanism has been discussed by Bate-Smith[2], Bauer, Birch and Hillis[3] and by King and Clark-Lewis[4]. The reaction, induced by hydrochloric acid, was regarded as a dehydration of the 3.4-diol group on the heterocyclic ring (loss of hydroxyl at 4 and hydrogen at 3), followed by oxidation[2–4] or by disproportionation[3,4].

Hitherto *leuco*anthocyanins of unknown structure and also flavan-3.4-diols were conveniently treated with aqueous 2 *N* hydrochloric acid[5], with aqueous 3 *N* hydrochloric acid/propan-2-ol (1 : 5) under pressure[6] or with hydrochloric acid butan-1-ol[4,7] mixtures at 100° C. In most cases the reaction was characterized by low yields of anthocyanidins formed. Logically, if it is correctly surmised that the initial reaction constitutes a dehydration[1–4] at the diol grouping, the formation of anthocyanidins should be promoted by anhydrous conditions. This theory has now apparently found support in the observation that exclusion of moisture from the reaction mixture effects an increase in the yield of anthocyanidins formed.

For example, 7.3′.4′.5′-tetrahydroxyflavan-3.4-diol[8] is converted into anthocyanidins in approximately 37–42 per cent yield by using anyhdrous $N/30 - N/50$ hydrochloric acid in propan-2-ol in an enclosed tube under pressure. By comparison, this flavan-3.4-diol (*leuco*robinetinidin) is converted into robinetinidin only, in 3 per cent yield in 3 *N* hydrochloric acid and 20 per cent yield[8] with 3 *N* hydrochloric acid/propan-2-ol under the conditions of Pigman *et al.*[6] Under anhydrous conditions the reaction is also far more rapid, and maximum yields of anthocyanidins result in 15–20 min. compared with 40 min. under previous conditions[6]. Other flavan-3.4-diols of type I behave similarly.

Under the new anhydrous conditions two anthocyanidins of similar coloration but with different rates of migration on paper chromatograms are generated from each flavan-3.4-diol. In all instances examined the anthocyanidin of lower R_F corresponds to that (II) generated under aqueous conditions, and the anthocyanidin of higher R_F is probably the corresponding 3-*iso*propyl ether derivative III (or possibly a 4-*iso*propyl ether of a new type of anthocyanidin). Ether formation with the 3 (or possibly the 4) position of the flavan-3.4-diol occurs prior to conversion into the corresponding anthocyanidin, and is promoted by anhydrous conditions established for the reaction. In the presence of 20 per cent moisture[6] the formation of the ether (III) is almost, but not entirely, inhibited, and mainly one anthocyanidin (II) results.

(III)

R = H or OH R_1 = *iso*Propyl

Pigman *et al.*[6] in 1953 first demonstrated the presence of *leuco*anthocyanins in some commercial tanning extracts, for example, wattle (*Acacia mollissima*), quebracho (*Schinopsis* spp.) and mangrove (*Rhizophora* spp.), and the new method represents a modification of their improved conditions. The tannins present in these extracts may be converted into anthocyanidins in 5–9 per cent, 13–21 per cent (*S. quebracho-colorado*) and 16·5 per cent (*R. mucronata*) yields respectively (cf. ref. 7). Details of a study of the reaction conditions, the reaction mechanism, and implications for the chemistry of condensed tannins will be published elsewhere.

Detection of Meprobamate on Paper Chromatograms

In a recent communication, Drs. A. Fiori and M. Marigo[1] described the identification of meprobamate by adsorption chromatography on chromatoplates. Their method is both complex and laborious compared with the technique of paper chromatography, but was advocated because meprobamate appeared to be insoluble in water and because there were no available methods for detecting it on paper.

Paper chromatography can, however, be used in the identification of this substance. Meprobamate is slightly soluble in water, and we have found that it may be detected on paper chromatograms by the hypochlorite modification[2] of the chlorination method first described by H. N. Rydon and P. W. G. Smith[3]. The paper is sprayed when dry, first with 1 per cent sodium hypochlorite, then with ethanol and finally with a mixture of equal volumes of 1 per cent starch and $M/20$ potassium iodide.

This method has been used for identifying meprobamate in the urine of a patient in coma, in whom the diagnosis had previously been in doubt. A report of this case, with details of the chemical methods by which the diagnosis was established, is being published elsewhere[4]. In this context, it is of interest that the chlorination method, which has numerous applications, has recently been used to detect barbiturates on paper chromatograms[5].

BIOCHEMISTRY and PHYSIOLOGY

Cellulose Acetate Membranes suitable for Osmotic Measurements

In a recent paper[1] it has been shown that 'Ultrafein filters allerfeinst', which the manufacturers state are composed of an unnamed cellulose ester, can be used to measure quite low number average molecular weights ($\overline{M}_n$). We have now found that membranes having similar osmotic properties can, in fact, be prepared from cellulose acetate.

The membranes are prepared by casting acetone solutions of cellulose acetate, containing *n*-amyl alcohol as precipitant[2], and allowing them to evaporate until nearly dry. The actual conditions for carrying out this operation appear to be rather critical, and so far a procedure giving absolutely reproducible membranes has not been evolved. However, by using the following method, membranes which show similar variations in osmotic properties to those found with the 'Ultrafein filters allerfeinst' can be prepared.

The following solution is made up: 5 per cent (w/w) cellulose acetate; 5 per cent (w/w) *n*-amyl alcohol; 90 per cent (w/w) acetone, and a volume containing enough cellulose acetate to give a 'membrane density' (that is, weight per unit area) of 0·005 gm./cm.^{2} is poured into a level glass dish and allowed to evaporate at room temperature in a cabinet free from draughts. As the membrane dries out, the surface first of all looks like orange peel and then goes opaque. For osmotic purposes the structure is fixed just before the membrane becomes opaque by pouring on ethanol. In a typical membrane, when the ethanol is poured on, three distinct zones appear: (1) a clear zone; (2) a white zone; (3) a white zone with dark spots. The effective part of the membrane is the white portion, since the clear areas (opaque before the addition of ethanol) have dried out too much and are usually impermeable, while the dark spots indicate pinholes which occur when the membrane has not dried out enough. The membranes are left in ethanol for at least 1 hr. to remove any residual amyl alcohol and are then conditioned to the required solvent; for example, in the case of benzene the membranes are left for periods of at least 1 hr. in (*a*) a 50 ethanol/50 benzene mixture and then (*b*) benzene.

The membranes used in the experiments described here were assembled in standard Zimm-Myerson type osmometers[1] and characterized by: (*a*) the solvent permeability, as measured by the rate of fall of solvent in the measuring capillary from a 10-cm. head; and (*b*) the solute selectivity as measured by the maximum osmotic pressures developed with a 1 per cent (w/w) solution of a 'commercial' polystyrene and/or a 0·025 per cent (w/v) solution of sucrose octaacetate (molecular weight 679).

In Table 1 results with typical and very selective membranes of both cellulose acetate and 'Ultrafein filters allerfeinst' are shown. It will be seen that the cellulose acetate membranes compare very favourably with the 'Ultrafein filters allerfeinst', having similar solute selectivities combined with slightly

Table 1. Comparison of 'Ultrafein Filters Allerfeinst' and Cellulose Acetate Membranes; Benzene Solutions at 30° C.

Membrane		Permeability	Selectivity

0·020	1·60	70	1·54	50	1·60	

higher solvent permeabilities. The very selective membranes can be used for determining quite low molecular weights and in Table 2 are shown the results obtained using membrane *CA*3/4 with an ionic polystyrene having $\overline{M}_n = 3,800$. Unfortunately, while it is comparatively easy to make membranes such as *CA*2/58, only a few membranes like *CA*1/68 and *CA*3/4 have so far been prepared. In these experiments benzene was used as solvent, but successful osmotic measurements have also been made in toluene and water.

The cellulose acetate used in the experiments was obtained from the British Drug Houses, Ltd.

I wish to thank Miss S. A. Monksfield and Miss H. M. Sankey for assistance with the experimental work. This work forms part of the research programme of the National Chemical Laboratory and is published by permission of the Director.

Liquid/Solid Content of Fats

The consistency of margarine and other commercial fats depends to a large extent on the relative amounts of liquid and solid fats present. The usual method for determining these values is by dilatation measurements and the dilatometer is used fairly considerably for this work. There are, however, certain inherent errors in this type of measurement. It is stated that the calculation of liquid/solid content from dilatometric data is either not possible with any degree of accuracy[1] or even that it is impossible[2] with complex mixtures of glycerides. This arises from the fact that a prior knowledge of the glycerides present is required and that mathematical adjustment is needed to take account of the different melting dilatations. Such prior knowledge is not always available.

We have recently found that the use of low-resolution nuclear magnetic resonance spectroscopy provides a new means for such determinations which eliminates many of the inherent errors of the dilatation method. In effect, use is made of the inherent disparity in the nuclear magnetic line-widths observed with liquids and solids. It is known that the shape of the hydrogen resonance line is influenced by the chemical and physical state of the sample and that the width is related to the mobility of the compound containing the hydrogen and to the field homogeneity. With solids the line-width is of the order of several gauss, while with liquids the line-width is very narrow and is determined by the inhomogeneity of the applied magnetic field[3].

An example of the method adopted is illustrated by the determination of the liquid content of simple mixtures of known amounts of tristearin and triolein (tristearin does not form a solid solution in the triolein phase). A bridged-T nuclear magnetic resonance spectrometer was used[4]. The magnetic field was modulated at a sinusoidal frequency of about 40 c./s. with a magnitude of about 30 milligauss, peak to peak. The line-width was determined by the inhomogeneity of the magnetic field and was about 100 milligauss at half-height. Under these conditions the derivative curve shows no signal due to the broad band of the solid, and a measure of the peak-to-peak height of the recorded derivative curve is a direct measure of the amount of liquid present. By comparing the peak-height for any of the mixtures with that for 100 per cent liquid, the liquid content can therefore be determined. Typical results are shown in Table 1. Similar work has also been carried out with other fat mixtures.

Table 1

Known percentage of liquid glyceride	Average percentage found
75·1	74·0
50·2	51·2
25·1	25·4

The new technique has the following advantages:

(*a*) Fats or mixtures may be examined in the state in which they are received, that is, without altering the structure by melting or crystallization.

(*b*) The results are independent of the particular composition of the fat, that is, no prior knowledge of the glycerides present is required.

(*c*) The results are independent of the polymorphic form of the solid present.

A full account of this work will be reported elsewhere.

Determination of Galactosediethylmercaptal and 3,6 Anhydrogalactosediethylmercaptal with the Anthrone and Seliwanoff Reagents

Some pure 3,6 anhydro-L-galactose was required as standard to determine the concentration of this sugar in several algal polysaccharides. Efforts to prepare it in a crystalline form were unsuccessful. Therefore the standard solution was made up from the 3,6 anhydro-L-galactosediethylmercaptal. Unfortunately the ethylmercaptan liberated on acid hydrolysis of the mercaptal interfered with colour formation in the anthrone and Seliwanoff tests. A similar interference was obtained with the diphenylamine reagent[1]. A method was developed to obtain from 3,6 anhydro-L-galactosediethylmercaptal, in quantitative yield, a solution of 3,6 anhydro-L-galactose free of ethylmercaptan. The object of this communication is to describe the method whereby sugar mercaptals can be analysed with colorimetric sugar reagents.

The galactose diethylmercaptal was prepared by Wolfrom's method[2] and 3,6 anhydro-L-galactosediethylmercaptal was obtained from the mercaptolysis of agar[3]. Anthrone reagent was dissolved in 80 per cent v/v sulphuric acid. 2 ml. of sugar were added to 10 ml. of anthrone reagent, mixed in an ice-bath and heated for 20 min. at 80° C. The conditions were optimum for the simultaneous determination of galactose and 3,6 anhydro-L-galactose in agar[4]. The conditions for the Seliwanoff test were those of Roe[5].

Solutions of galactose diethylmercaptal (159 μgm./2 ml. water) and 3,6 anhydro-L-galactosediethylmercaptal (82·7 μgm./2 ml. water) were analysed with anthrone and Seliwanoff reagents. The optical densities with the anthrone reagent of the two mercaptals were, respectively, 10 per cent and 98 per cent less than those of equimolar quantities of galactose and 3,6 anhydro-L-galactose (Table 1). With the Seliwanoff reagent the optical density of 3,6 anhydro-L-galactosediethylmercaptal was 6 per cent less than that of 3,6 anhydro-L-galactose.

Table 1. OPTICAL DENSITIES OF MERCAPTALS AND SUGAR RESIDUES

Sugar	Concentration (μgm.)	Anthrone reagent 625 mμ	Seliwanoff reagent 520 mμ
Galactose	100	0·400	0·015
Galactose from galactose diethylmercaptal*	100	0·395	—
Galactose diethylmercaptal	159	0·360	—
3,6 Anhydro-L-galactose from 3,6 anhydro-L-galactose-diethylmercaptal	50	0·410	0·425
3,6 Anhydro-L-galactose diethylmercaptal	82·7	0·010	0·400

* μgm. of sugar obtained in demercaptolysis with 10 moles mercuric chloride at 50° C. for 1 hr.

In the colorimetric tests the hydrolysis of the mercaptals in hot acids involves removal of the ethylmercaptan and formation of the colour complex with the decomposition products of the sugar residues. The results showed that the formation of colour in the anthrone reaction was inhibited by traces of ethylmercaptan. Therefore the optical density obtained with the anthrone reagent was used as an index to determine the rate and degree of demercaptolysis.

The following method was used for the demercaptolysis of the sugar mercaptals. 5 ml. of a stock solution which contained 794·5 μgm. of galactose diethylmercaptal per ml. or 413·5 μgm. of 3,6 anhydro-L-galactosediethylmercaptal per ml., a microspatula scoop of cadmium carbonate and 10 moles of mercuric chloride/mole of sugar were added to a 50-ml. volumetric flask. The mixture was heated for ½ hr. at 50° C., diluted to volume and then passed through a sintered glass filter to remove the mercury mercaptide.

The conditions reported in the literature for the demercaptolysis of 3,6 anhydro-L-galactosediethylmercaptal require 1·75 moles of mercuric chloride/mole of sugar, heated for 5 hr. at 50° C., yield not reported[6], and 2 moles of mercuric chloride/mole of sugar held for 3 hr. at room temperature with a 56 per cent yield[3]. The results in Tables 2 and 3 showed that at least 4 moles of mercuric chloride were required to obtain complete removal of the ethyl mercaptan. When galactose diethylmercaptal and 3,6 anhydro-L-galactosediethylmercaptal were treated with 10 moles mercuric chloride for ½ hr. at 50° C. a quantitative yield of galactose and maximum colour formation with 3,6 anhydro-L-galactose was obtained. A large excess of mercuric chloride, 100 moles, had no effect on the optical density of solutions of galactose, fructose and 3,6 anhydro-L-galactose with the anthrone and Seliwanoff reagents.

Table 2. EFFECT OF MERCURIC CHLORIDE ON THE DEMERCAPTOLYSIS OF 3,6 ANHYDRO-L-GALACTOSEDIETHYLMERCAPTAL*

Mercuric chloride (moles)	2	3	4	10	100
D. anthrone reagent	0·362	0·390	0·405	0·408	0·405

* Reaction for 1 hr. at 50° C. 50 μgm. of 3,6 anhydro-L-galactose.

Table 3. RATE OF DEMERCAPTOLYSIS OF 3,6 ANHYDRO-L-GALACTOSE-DIETHYLMERCAPTAL*

Time in hr. at 50° C.	½	1	12	30 min. at 25° C.
D. anthrone reagent	0·405	0·408	0·410	0·350

* Reaction 10 moles of mercuric chloride/mole of sugar 50 μgm. of 3,6 anhydro-L-galactose.

In summary, a method has been developed to use colorimetric sugar reagents for the analysis of mercaptals. The sensitivity of the anthrone reaction to ethylmercaptan provided a simple index to determine conditions for complete demercaptolysis of sugar mercaptals.

I wish to acknowledge the assistance of the late Dr. A. N. O'Neill in the preparation of the mercaptals.

Oxidative Phosphorylation in the Chick Embryo

SYNTHESIS of high-energy phosphate bonds was measured by the estimation of phosphorus : oxygen ratios. The materials used were 7–9 day old chick embryos of a hybrid White Leghorn ♀ × New Hampshire Red ♂. Except for the step *iso*citrate → succinate, the estimations were done on the mitochondrial fraction, prepared according to the method of Hogeboom and Schneider[1]. Oxygen consumption was measured by the Warburg technique, using 0·1 *M* phosphate buffer at *p*H 7·4 with the addition of adequate co-factors and substrates[2]. Phosphorus estimations were carried out according to the method of Lowry and Lopez[3].

Table 1 summarizes our results. Steps, pyruvate → acetyl coenzyme A, and malate → oxalacetate show 3·0 as probable ratios in the cell, whereas phosphorus : oxygen ratios of 2·0 are characteristic of the remaining steps. Estimations of the step *iso*citrate → succinate on mitochondria showed a very low ratio, in the majority of cases less than 1·0; the same occurred when citrate was used as substrate. On the other

Table 1. Phosphorus : Oxygen Ratios of Different Steps within the Krebs Cycle

(In parenthesis : number of experiments)

•	Phosphorus : Oxygen ratio	
	Observed	Probable in intact cell
Pyruvate → Acetyl coenzyme A	2·1 (15)	3·0
*iso*Citrate → Succinate	2·0 (16)*	3·0
Alpha-ketoglutarate → Succinate	1·9 (19)	2·0
Succinate → Fumarate	1·8 (16)	2·0
Malate → Oxalacetate	2·6 (13)	3·0

* Obtained on homogenates

hand, when homogenates were used, the phosphorus : oxygen ratio increased to 2·0 with *iso*citrate (14 experiments) and 2·2 with citrate (10 experiments), which point to a probable phosphorus : oxygen ratio of 3·0 inside the cell. In this respect the embryonic mitochondria behave differently from those of the rat liver ; Copenhaver and Lardy[4] showed an estimated phosphorus : oxygen ratio 2·6 for citrate. Our estimations on the rat liver mitochondria gave an average of 2·1 with citrate as substrate.

Full details of this work will be published elsewhere. It was aided by U.S. Public Health Service Grant *C*–2296 (*C*7).

Synthesis of Amylose by Potato *D*-Enzyme

The synthesis of the chain-forming α-1 : 4-bonds of potato starch (amylose + amylopectin) has for long been ascribed to phosphorylase acting on glucose-1-phosphate and a preformed starch-like primer[1]. We now report the synthesis of amylose-like material by another enzyme system from potato. This synthesis makes use of *D*-enzyme, discovered in 1953 by Peat and co-workers[2]. *D*-enzyme catalyses the reversible disproportionation of maltodextrins, the glucose oligosaccharides containing the α-1 : 4-linkage. For example, maltotriose is acted on to give, as the first products of reaction, glucose and maltopentaose, and at equilibrium glucose and a whole series of maltodextrins are present. However, with maltotriose as the initial substrate, none of the synthetic oligosaccharides is of sufficient length to form a coloured complex with iodine. The minimum length for colour formation is at least 12 glucose units[3]. Incubation of *D*-enzyme with a maltodextrin and glucose lowers the average length of the polymer because of transfer of some of its glucose residues to the added glucose. It was realized that a reversal of this procedure, the removal of glucose, should increase the length of the polymers and might ultimately result in the synthesis from a small maltodextrin molecule of an iodine-staining, amylose-like polysaccharide. If, in addition to *D*-enzyme, the potato is equipped with such a glucose-removing enzyme system, then it is presumably capable of synthesizing amylose by a route other than that provided by phosphorylase. A suitable glucose-removing system is hexokinase and adenosine triphosphate, and hexokinase is known to be in the potato[4]. This will convert glucose into glucose-6-phosphate, and *D*-enzyme does not transfer chain segments from maltodextrins to the sugar phosphate as it does to glucose[5]. The system (maltodextrin + *D*-enzyme + hexokinase + adenosine triphosphate) should therefore bring about amylose synthesis. This has been achieved.

We have preferred to use yeast hexokinase in the present experiments because it can be obtained in a better state of purity than the potato enzyme. In the first instance *D*-enzyme was incubated with a mixture of maltodextrins (malto-pentaose, -hexaose and -heptaose) from which some of the products of *D*-enzyme action alone are long enough to stain with iodine[2]. The same system with added hexokinase and adenosine triphosphate produced iodine-staining material at more than twice the rate. The experiment was repeated with maltotetraose, which with *D*-enzyme alone does not give iodine-staining products. Fig. 1 depicts the course of reaction of *D*-enzyme + maltotetraose in the presence and absence of the glucose-phosphorylating system. When glucose was continuously removed as the 6-phosphate there was an abundant production of iodine-staining polysaccharide, and correspondingly adenosine triphosphate disappeared.

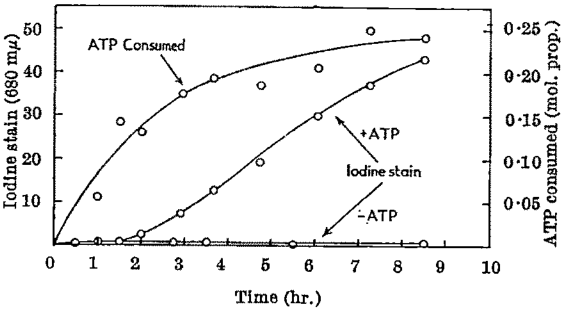

Fig. 1. Synthesis of amylase from maltotetraose. *D*-enzyme was incubated at 25° C. with hexokinase and maltotetraose in the presence and absence of adenosine triphosphate (ATP). The *p*H was maintained at 7·2 by the frequent addition of sodium hydroxide

The suggestion has been made[6] that the potato may use both phosphorylase and *D*-enzyme to synthesize amylose, the product from phosphorylase remaining as amylose and from *D*-enzyme being converted into amylopectin by *Q*-enzyme. Experiments are now in progress to demonstrate the working of such a system *in vitro*.

This work was made possible by grants from the Agricultural Research Council, to which we express our thanks. We also thank Dr. K. Rees for a gift of hexokinase.

Cotinine: an Oxidation Product of Nicotine formed by Rabbit Liver

A MAJOR advance in the elucidation of nicotine metabolism was the demonstration by McKennis *et al.*[1] that dogs receiving nicotine excreted small amounts of γ-(3-pyridyl)-γ-methylaminobutyric acid and its lactam, cotinine. These workers favoured the view that cotinine was formed in urine by spontaneous lactamization of the acid. However, they also suggested that cotinine might be an intermediate in nicotine metabolism which was hydrolysed to the acid *in vivo*.

We have previously reported[2] that nicotine is metabolized in liver microsomes by an enzyme system requiring reduced triphosphopyridine nucleotide and oxygen. We now wish to report that a major product of nicotine oxidation by liver preparations is cotinine.

3 μmoles of nicotine were incubated with a supernatant fraction of rabbit liver (prepared at 9,000*g*), supplemented with triphosphopyridine nucleotide (0·5 μmole), glucose-6-phosphate (25 μmoles) and nicotinamide (0·1 μmole), for 90 min. at 37° C. under oxygen. Unchanged nicotine was extracted into heptane and assayed spectrophotometrically (259 mμ in 0·1 *N* hydrochloric acid). Cotinine remaining in the aqueous phase was then extracted into chloroform. After washing with 0·1 *M* citrate buffer, *p*H 5·0, to remove an unidentified metabolite, the chloroform phase was extracted with 0·1 *N* hydrochloric acid. Material in the acid phase, accounting for about half the metabolized nicotine, was tentatively identified as cotinine by ultra-violet absorption ($\lambda_{max.}$ 262 mμ), comparative distribution ratios[3] and paper chromatography with three solvent systems.

The metabolite was isolated as follows: nicotine (1,200 μmoles) was incubated with 1,200 ml. of liver supernatant fraction and other components in proportion. Cotinine was extracted into chloroform as described above and the organic phase washed with citrate buffer, *p*H 5·0. After evaporation of the chloroform at room temperature under nitrogen, the residue was subjected to an eight transfer countercurrent distribution between equal volumes of chloroform and 0·6 *M* citrate buffer, *p*H 3·5. Contents of tubes 3–6 containing material of similar partition ratios were pooled, alkalinized and the total basic material extracted into the chloroform phase. The chloroform was evaporated and the residue taken up in ether. After drying the ether phase with sodium sulphate, addition of 60 per cent perchloric acid in ethanol (1 : 1) gave the perchlorate derivative, m.p. 218–219°. The melting point was not depressed on admixture with authentic cotinine perchlorate[4], m.p. 218–219°. Analysis—calculated for $C_{10}H_{13}N_2O_5$: C, 43·41 ; H, 4·74 ; found : C, 43·62 ; H, 5·01. The infra-red spectrum (in potassium bromide pellet) was identical with that of authentic cotinine perchlorate.

When 15 mgm./kgm. of nicotine were administered intramuscularly to rabbits, small amounts of cotinine equivalent to about 10 per cent of the dose were excreted in the urine. Similarly, less than 10 per cent of cotinine administered to rabbits (15 mgm./kgm.) intravenously was found in the urine. Since only small amounts of cotinine are excreted after administering nicotine or cotinine, it is possible that the latter compound is a major metabolite of nicotine *in vivo*.

It seems possible that the first step in the oxidation of nicotine is hydroxylation, followed by oxidation to cotinine and hydrolysis as follows :

Composition of Lipids isolated from the Aorta, Coronary Arteries and Circulus Willisii of Atherosclerotic Individuals

INVESTIGATIONS of lipid deposits connected with atherosclerosis have usually been concerned with the lipids from the plaques formed in the intima of the aorta[1]. Although the condition of the aorta is a guide to the progress of the disease, dysfunction due to atherosclerosis is most liable to occur in the smaller arteries, especially coronary and cerebral arteries. It has generally been assumed that lipid deposition in these arteries occurs in a similar way to that in the aorta. If this is so, the composition of the lipids deposited should be approximately the same. Lipids extracted from different atheromatous arteries have been examined in order to test this assumption.

The amount of lipid extractable from coronary or brain arteries is extremely small (as indeed it is for healthy aortas), but methods have recently been developed in this laboratory for the separation of as little as 70 mgm. of tissue lipids into phospholipids, sterol esters, triglycerides, free fatty acids and free sterols. The first three groups can then be saponified and the resultant fatty acid mixtures, as well as the

Table 1. COMPOSITION OF LIPIDS FROM INDIVIDUAL ARTERIES

	Aorta (case *A*)	Circulus Willisii (case *A*)	Coronary arteries (case *A*)	Coronary arteries (case *B*)	Coronary arteries (case *C*)
Yield of lipids*	15·9	10·7	23·7	21·4	15·0
Composition (per cent)					
Phospholipids	26·8	29·5	16·7	16·7	19·2
Free fatty acids	0·9	3·6	1·9	2·8	3·4
Free cholesterol	22·6	7·6	12·2	11·2	21·6
Cholesterol esters	36·4	46·9	21·4	25·9	28·1
Triglycerides	13·9	12·4	49·0	58·6	27·6

* As a percentage of the weight of the freeze-dried tissue.

free fatty acids, methylated and analysed by vapour-phase chromatography.

The material for the investigation (case *A*) of which the results are shown in Table 1 came from a man eighty-eight years of age; the aorta showed an advanced stage of atherosclerosis, and the coronary and brain arteries were atheromatous.

The adventitia and outer part of the media were removed from the aorta, the coronary arteries and the circulus Willisii. The remaining material was cut into small pieces, and the three preparations were freeze-dried before being extracted with methanol–chloroform (1 : 2) at room temperature.

After purification of the lipids by passage of the concentrated methanol–chloroform solution through a column of powdered cellulose[2], the phospholipids were separated from the other lipids by dialysing the latter through a rubber membrane[3], the free fatty acids removed by alkaline extraction and the remaining three groups separated by silicic acid chromatography (essentially according to Borgström[4]). The phospholipids were saponified, first with anhydrous methanolic hydrochloric acid, then with ethanolic potassium hydroxide; the triglycerides and sterol esters were saponified with ethanolic potassium hydroxide alone. The fatty acid fractions and the free fatty acids were converted to their methyl esters and are to be examined by gas chromatography.

The composition of the lipids from the different arteries is shown in Table 1. The amounts of different lipid sub-groups are given as percentages of the total lipid; those for free cholesterol, cholesterol esters and triglycerides were determined colorimetrically. The most striking result is the high percentage of triglycerides in the coronary arteries, compared with the aorta. That this was not an isolated phenomenon characteristic only of case *A* is shown by the last two columns of Table 1, where two further analyses of atherosclerotic coronary arteries (from men of 61 and 66 years, respectively) reveal a high triglyceride content. The triglyceride level of the third example (case *C*) was not as high as the other two, but was much higher than we have ever found in lipids from aortas (cf. Table 2).

Table 2. COMPARISON OF LIPID COMPOSITION OF DIFFERENT ARTERIES

	Aorta stage 0* (2 cases)	Aorta stage I* (5 cases)	Aorta stage II* (6 cases)	Aorta stage III* (5 cases)	Coronaries (3 cases)	Circulus Willisii (1 case)
Yield of lipids†	3·0	4·2	8·5	13·1	20·0	10·7
Composition (per cent):						
Phospholipids	65·8	52·5	33·3	33·6	17·5	29·5
Free fatty acids	5·2	5·8	3·4	1·4	2·7	3·6
Free cholesterol	7·7	11·8	19·1	19·8	15·0	7·6
Cholesterol esters	4·7	14·0	35·1	40·2	25·1	46·9
Triglycerides	15·0	15·4	12·0	8·6	45·1	12·4

* The aortas are classified (ref. 5) according to the appearance of the intima. Stage 0, aorta apparently free from disease; stage I, fatty streaks or spots, distinct plaques of not more than 2 mm. in diameter; stage II, plaques more than 2 mm. in diameter; stage III, complicated lesions (ulcera).

† As a percentage of the weight of freeze-dried tissue.

In contrast with the coronary arteries, the circular Willisii had a triglyceride content falling within the range observed for aortas. Both the total amount of lipids extractable from the tissue and the percentage of triglycerides in the lipids were approximately equal to those from a stage II aorta. The unusual feature in this artery was the comparatively high content of cholesterol esters, coupled with the extremely low level of free cholesterol.

No explanation of the differences is offered at present; but these preliminary findings are reported as an indication that theories concerning atherosclerosis based on observations of the aorta may have to take into account extra factors when they are applied to other arteries.

Determination of Transaminase Activity in Dogs' Serum and Lymph after Hepatic Damage due to Acute Biliary Obstruction

IT is known that glutamic-oxaloacetic acid transaminase (GOT) and glutamic-pyruvic acid transaminase (GPT) are increased in sera of patients suffering from certain liver diseases[1]; but there are scarcely any data available about the pathways of these enzymes. We have therefore studied the changes of the concentration of transaminase of hepatic origin at various points of the blood and lymphatic circulation after damage to the liver caused experimentally by biliary obstruction.

The experiments were carried out on dogs under anæsthesia with chloralose (0·1 gm. per kgm. body-weight). We collected simultaneously samples of sera from the femoral artery and hepatic veins on one hand and thoracic duct and hepatic lymph on the other. The concentration of transaminase was determined by Umbreit's method[2]. Damage to the liver was produced by ligating the common bile duct and injecting 100–150 ml. of 5 per cent sodium chloride solution. The concentrations of

Table 1. Normal Values of the Activities of Glutamic-oxaloacetic and Glutamic-pyruvic Acid Transaminases in Dogs

	Art. fem. ser.		V. hep. ser.		D. thor. lymph		Hepatic lymph	
	GOT	GPT	GOT	GPT	GOT	GPT	GOT	GPT
Mean	70	53	78	80	67	52	121	70
Extreme values	23–134	11–89	20–124	20–195	7–126	8–119	80–136	38–125
Number of cases	19	18	18	15	20	19	5	4

glutamic-oxaloacetic acid transaminase and of glutamic-pyruvic acid transaminase were determined 15 min. before and 15 min. after the injection.

Table 1 summarizes the values found in normal controls, and Fig. 1 illustrates the values found after hepatic damage.

Compared with the values of the controls, the concentrations found after hepatic damage are significantly greater in all our experiments.

So far as we know, no data on transaminase activity in the hepatic veins or in the lymph of the various lymphatic ducts have been published. According to our results, the activities of both glutamic-oxaloacetic and glutamic-pyruvic acid transaminase are considerably increased in every fraction of the blood and lymph after hepatic damage; the actual rise is to some extent variable. (In the experiment represented in Fig. 1 the greatest change occurred in the serum from the hepatic vein.)

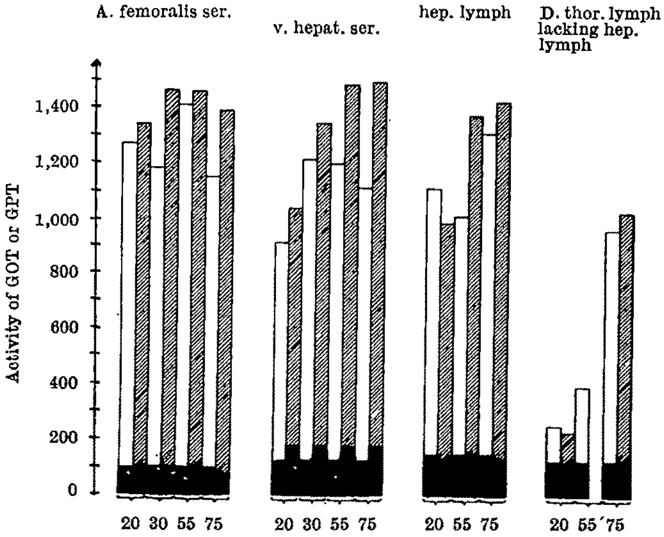

Fig. 1. Activity of glutamic oxaloacetic acid transaminase (white); and of glutamic pyruvic acid transaminase (hatched); mean of control periods (black)

Histological examination of the liver tissue showed intense hyperæmia, œdema and damage to the liver cells (vacuoles, hyalin degeneration).

Effect of Insulin on Sulphydryl Groups in Muscle

It has been shown that the free —SH content of nerve tissue increases under the influence of stimulation. This suggested the possibility that the number of titratable —SH groups may be directly or indirectly related to the ratio of potassium to sodium ions in the cell and consequently to its surface potential[1,2].

Flückiger and Verzár[3], Zierler[4] and Creese, D'Silva and Northover[5] have observed that addition of insulin *in vitro* to rat-muscle preparations causes gain in potassium ions and loss of sodium ions by the cell and an increase of its resting potential. It seemed, therefore, interesting to investigate whether these changes would be accompanied by a corresponding fall in titratable —SH groups.

Diaphragms were removed from male *CF* Wistar rats (100–145 gm.). Each hemidiaphragm was washed, and suspended in 150 ml. of a glucose–saline medium buffered to *p*H 7·4 and containing 6·15 μmoles potassium ion/ml. To one of the hemidiaphragms was added insulin ('Iletin', Lilly) at a concentration of 0·1 unit/ml.; the other served as a control. A mixture of 95 per cent oxygen and 5 per cent carbon dioxide was bubbling through both preparations for 2 hr. at room temperature.

Content of potassium ions was determined in eight pairs of hemidiaphragms after 2 hr. incubation. The muscle was blotted and submitted to the wet-ashing procedure described by Ballantine and Burford[6]; content of potassium ions was measured by means of a flame photometer using an internal standard. The mean potassium ion content of the insulin-treated hemidiaphragm was 130·4 (±33·5 *S.D.*) μmoles/gm. of wet weight; the control muscles contained 82·3 (±32·8) μmoles/gm. The increase in potassium ion content, 48·1 μmoles, is 58·5 per cent of the controls.

Thirty pairs of hemidiaphragms were used for the determination of —SH groups. The tissue was frozen with dry-ice, ground in a Potter–Elvehjem homogenizer and extracted with the suspension medium. After centrifugation at 4,000 r.p.m. for 20 min., —SH groups were determined in the supernatant by means of the amperometric titration method of Benesch, Lardy and Benesch[7]. In 26 experiments the —SH content of the insulin-treated hemidiaphragm decreased by an average of 22·1 per cent. The control muscle contained 5·32 (±1·08 *S.D.*) μmoles/gm. wet weight; under the influence of insulin the —SH groups fell to 4·14 (±0·84) μmoles. The difference is significant at the level of $P = 0{\cdot}05$–$0{\cdot}02$. In four experiments —SH groups increased by an average of 1·22 μmoles/gm.: it could not be ascertained whether these results were due to a technical failure or to some particular condition of the animals.

In some experiments, the extract was dialysed in a shaking dialyser against 25 vol. of the extraction medium. As in brain tissue[2], the major proportion (80 per cent) of the —SH groups in muscle was bound to non-dialysable molecules, presumably to proteins. The decrease caused by insulin affected about equally the dialysable and non-dialysable sulphydryl fractions.

The fact that insulin causes hyperpolarization of the cell surface, increase of the ratio of potassium to sodium ions and decrease of —SH groups can be interpreted in various ways. In terms of the membrane theory, it could be assumed that insulin, by its action on metabolic processes, increases the efficiency of the ionic 'pumps' or that it acts directly on the membrane and alters its permeability properties. The latter action is assumed to operate in facilitating the entry of glucose into the cell[8]. There is also some evidence that glycogen fixes potassium ions[9] so that increased glycogen synthesis may result in higher intracellular potassium.

In view of certain observations on protein configuration in resting and stimulated cells, insulin can be assumed to act primarily by modifying the structure of certain protein molecules. Stimulation and subsequent depolarization, with lowered ratio of potassium to sodium ions, are accompanied by an 'unmasking' of titratable —SH groups and other ionized side-groups, suggesting a general 'loosening' of the structure of protein molecules[1,2,10]. In the opposite direction, hyperpolarization, with raised intracellular ratio of potassium to sodium ions could be characterized by a decrease in ionized side-groups and tendency to a more rigid protein configuration. Further investigations are being conducted to determine whether modifications of protein structure represent a determining factor in the mechanism of cellular rest and excitation.

Reduction of Neotetrazolium Chloride by Vitamin K_3

MENADIONE (vitamin K_3, 2-methyl-1.4-naphthaquinone) has become increasingly associated with pathways of electron transfer. It has been implicated in the nitrate reductase sequence; in the processes of photosynthetic phosphorylation; in a non-phosphorylative oxidative pathway; in menadione reductase and in the general respiratory chain and associated processes of oxidative phosphorylation (cf. ref. 1). Menadione has recently been associated with an enzyme sequence connecting the oxidation of succinate with the reduction of neotetrazolium chloride[1]. The vitamin K_3 involved in such reactions can be followed by spectrophotometric rate measurements[2].

This communication shows that it is also possible to demonstrate that vitamin K_3 is involved in redox reactions by adding neotetrazolium chloride; reduced menadione reacts directly and non-enzymically with neotetrazolium chloride at *p*H 7·4 and 37° C., yielding the intensely coloured insoluble formazan. As stated by Shelton and Rice[3], the absorption maximum of the formazan varies with the method of reduction: enzymic reduction yields a product with a maximum absorption at 510 mμ; chemical reduction (for example, by reduced menadione or dithionite) yields a product with an absorption maximum at 540 mμ.

In the following experiments the reaction mixture used contained 1 ml. of a phosphate – versene mixture (1·0 ml. phosphate buffer, *p*H 7·4, 0·1 molar : 0·05 ml. sodium versenate, *p*H 7·4, 0·1 molar) and 0·15 ml. of 1 per cent neotetrazolium chloride. Other additions mentioned in Table 1 were made in a volume of 0·1 ml. Incubation was at 37° C. and the formazan was extracted with 4 ml. of ethyl acetate; the extinction was obtained using a Hilger 'Uvispek' spectrophotometer. Vitamin K_3 was added as a suspension in phosphate buffer, bovine plasma albumin and ethanol.

Table 1. EXTINCTION READ AT 540 Mμ IN A 'UVISPEK' SPECTROPHOTOMETER

Path-length 1 cm., incubation time 30 min. except for reduced menadione (5 min.), and cysteine + vitamin K_3 (15 min.); reagents and volumes described in the text. All values refer to the addition of 1 μmole of reagent

Addition	Extinction	Addition	Extinction
Menadione	0·007	Ascorbic acid + vitamin K_3	0·225
Reduced menadione	0·237	Glutathione + vitamin K_3	0·003
Ascorbic acid	0·066	Cysteine + vitamin K_3	0·960
Glutathione	0·002	Reduced diphosphopyridine nucleotide + vitamin K_3	0·036
Cysteine	0·009	Vitamin K_1 + ascorbic acid	0·123
2,3 Dimercapto-1-propanol	1·490	Vitamin E + ascorbic acid	0·091
Hydroquinone	0·000		
Reduced diphosphopyridine nucleotide	0·000		
Vitamin K_1	0·015		
Vitamin E	0·006		

Reduced menadione was prepared as described by Fieser[4]; a grey powder was obtained which had absorption maxima at 241 and 330 mμ as mentioned by Colpa-Boonstra and Slater[2]. Direct reduction of neotetrazolium chloride by the following reagents was also tried: reduced diphosphopyridine nucleotide (Boerhinger, 90 per cent pure); glutathione (Distillers Co., Ltd.): ascorbic acid (Roche); cysteine; 2,3 dimercapto-1-propanol (BAL, Boots Pure Drug Co., Ltd.); hydroquinone; vitamin E (L. Light and Co.); vitamin K_1 (Roche).

Other than reduced menadione, only 2,3 dimercapto-1-propanol reacted directly with neotetrazolium chloride to any substantial degree; slight production of formazan was observed with vitamin C (Table 1). Several of the reagents which did not reduce neotetrazolium chloride directly, were found to reduce menadione, which then led to the formation of formazan. For example, cysteine reduced menadione with a consequent formation of formazan on incubation, in spite of the fact that cysteine (and other similar compounds, for example, glutathione) combines readily with menadione under the conditions used to yield 3-substituted naphthaquinones. Under the conditions used (in *p*H 7·4 phosphate buffer : versene) the photochemical reduction of neotetrazolium chloride catalysed by cysteine with either riboflavin or riboflavin phosphate[5] was negligible.

The reduction of vitamin K_3 by vitamin C appears to occur to a considerable extent, indicating that the following reaction is displaced to the right in the presence of neotetrazolium chloride :

$$\text{ascorbate} + \text{menadione} \rightarrow \text{dehydroascorbate} + \text{reduced menadione}$$

This reaction between vitamin C and menadione is stimulated by tissue suspensions[1], but whether this stimulation is enzymic in character must await further investigation. The stimulatory power of homogenates is relatively insensitive to boiling. The stimulatory power of both rat liver and rat mammary gland homogenates is largely concentrated in the soluble fraction after removing the mitochondria and microsomes by differential centrifugation in 0·25 molar sucrose.

Reduced diphosphopyridine nucleotide reacted only slightly, if at all, with menadione to yield reduced menadione; reduced diphosphopyridine nucleotide had no direct effect on neotetrazolium chloride, as has been reported by Zöllner and Rothemund[6]. Typical results are shown in Table 1.

It seems possible, therefore, that in certain cases the fact that vitamin K_3 is involved in redox reactions can be demonstrated by the ready interaction of reduced menadione with neotetrazolium chloride.

I am grateful to Dr. A. L. Greenbaum and D. N. Planterose for helpful comments and suggestions; this work was carried out during the tenure of a Beit Memorial Fellowship.

Effect of β-Hydroxybutyrate Injections on the Pancreatic Activity of Guinea Pigs

β-HYDROXYBUTYRATE has been found to cause hyperglycæmia, glycosuria and lowered glucose tolerance in guinea pigs and rabbits when injected in gradually increasing doses for some time[1,2]. On injection in rabbits, this compound produces an initial state of hypoglycæmia followed in the long run by permanent hyperglycæmia. That this may be due to an initial state of hyper-insulinism, followed by hypo-insulinism due to an overwork atrophy of the *B*-cells, caused by continued stimulation has been suggested[3-6].

Since β-hydroxybutyrate is an important intermediary metabolite, its effect on the normal pancreas is evidently very interesting, and the present series of investigations have therefore been started to elucidate its mechanism of action. The present report indicates the effect produced by continued injections of β-hydroxybutyrate (sodium salt) on the amylolytic and insulin activity of the pancreatic tissue of guinea pigs.

The preliminary experiments reported here were carried out on two groups of guinea pigs. One group was kept as control, and the animals of the other group were given injections of sodium β-hydroxybutyrate (L. Light and Co., Ltd.). The initial dose was 50 mgm. per animal, and this was gradually increased to 100 mgm. per animal. At regular intervals the pancreas was removed from two animals of each group and a portion of pancreatic tissue assayed for amylase activity by Willstätter's method[7]. Another portion of the tissue was extracted for insulin[8] and the extracted insulin assayed on rabbits by the method of Burn[9]. The results are given in Table 1.

Table 1. AVERAGE VALUES OF PANCREATIC AMYLASE AND INSULIN OF GUINEA PIGS SUBJECTED TO INJECTIONS OF β-HYDROXYBUTYRATE (SODIUM SALT)

No.	Days of injections	Amylase activity mgm. of maltose/gm. of dry pancreas	Insulin potency (percentage reduction/gm. pancreas)
1	0 (control)	654·1	14·72
2	12	596·7	86·10
3	25	457·2	—
4	36	100·8	30·6

Table 1 reveals that the pancreatic amylase activity decreases with gradual increase in the dosage of β-hydroxybutyrate injections, whereas the insulin potency shows an initial increase and is then followed by a decrease. The decrease in pancreatic amylolytic activity may be due to a possible lowering of the rate in the proteosynthetic activity of the acinar cells as a result of a possible pharmacological response produced by β-hydroxybutyrate, or it might be due to a physiological response of the organ to maintain the overall enzyme–hormone balance or both. The changes in insulin potency as observed are in conformity with the order of earlier observations (*loc. cit.*), namely, initial stimulation of *B*-cells followed by a possible overwork atrophy as a response to β-hydroxybutyrate injections.

Leucine Aminopeptidase Activity in Mast Cells

DURING investigations of the behaviour of leucine aminopeptidase activity of blood-serum in patients with dermatoses and tumours[1-3], in a case of diffuse skin mastocytosis of a new-born, we detected heightened activity of leucine aminopeptidase. After mechanical friction of the affected skin, greater activity of leucine aminopeptidase occurred. From this we supposed a release of leucine aminopeptidase from the mast cell infiltrates of the skin. As is well known, in urticaria pigmentosa mechanical irritation of the skin lesions give rise to a degranulation of mast cells[4,5] with liberation of histamine and serotonin. Indeed, there is no doubt that mast cells contain the enzyme leucine aminopeptidase. Using Burstone and Folk's histochemical method[6], we were able to demonstrate a strong positive cytoplasmic

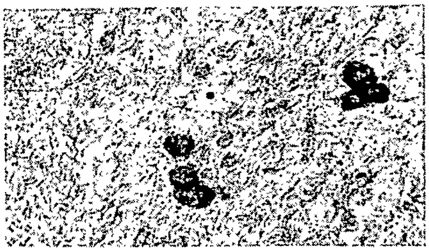

Fig. 1. Positive leucine aminopeptidase reaction in mast cells of rat mesentery

leucine aminopeptidase reaction in the mast cell infiltrates of the cutis in the above-mentioned case. Also in the mesentery of rats, mast cells likewise show a weak positive but distinct cytoplasmic leucine aminopeptidase reaction (Fig. 1), while other connective tissue cells are free of histochemically demonstrable activity of leucine aminopeptidase. To answer the question, whether with degranulation of mast cells there is a release of leucine aminopeptidase in the surrounding tissue, some experiments on rats were performed. Following Fawcett's method[7] for the release of histamine by mast cells, eight black rats (150–200 gm.) were killed and, after being bled, the abdomen was opened, the mesentery detached in its entirety at the root and separated from the intestine. After incubation in 2 ml. aqua bidest. or Tyrode's solution for 20 min. at 20° C. in 0·5 c.c. of the filtrate, the activity of leucine aminopeptidase was determined by a modified method of Green *et al.*[1]. Histological controls showed no greater morphological alterations of the mast cells by treatment with Tyrode's solution; however, after treatment by aqua bidest., the well-known osmotic rupture of the mast cells with degranulation[5,7] resulted (Table 1).

It is significant that activity of leucine aminopeptidase was demonstrable after treatment with Tyrode's solution. It is an open question whether or not this activity is connected with a release by mast cells. However, it should be noted that in a pretreated mesentery (Tyrode's solution or aqua bidest.) histochemically a real positive reaction of leucine aminopeptidase in mast cells could not be found. After osmotic disruption of the mesenteric mast cells by incubation in aqua bidest., the increase of activity of leucine aminopeptidase in the incubation fluid was about 100 per cent. This shows that osmotic rupture of the mast cells is concomitant with a release of leucine aminopeptidase.

It is still not possible to say, however, whether leucine aminopeptidase would be released in the process of physiological degranulation. Only suggestions can be made concerning the significance of leucine aminopeptidase in mast cells. Leucine aminopeptidase itself is probably not a uniform enzyme, but a mixture of di- and poly-peptidases[8]. Some observations[9,10] suggest that proteolytic enzymes, including leucine aminopeptidase, may be of importance in the process of liberation of heparin from native lipoprotein-complex[11,12] and perhaps also from the release of histamine or hydroxytryptamine. Also there may exist a relation to anaphylactic reactions, in which not only morphological changes in mast cells (degranulation) but also a higher activity of proteolytic enzymes can be found[13–15].

New Inhibitor and Erythrocyte Receptor Substances for Certain Asian Strains of Influenza Virus

Several investigators[1–5] and ourselves[6,7] have shown that individual Asian strains of influenza *A* virus can be divided into two groups on the grounds of their sensitivity to inhibitors of hæmagglutination. The so-called 'non-avid'[5] or *Q*-phase[8] strains are not inhibited by non-immune sera, and only moderately by homologous hyperimmune sera. On the other hand, both non-immune and immune serum inhibitors are highly active against the 'avid' or *R*-phase strains.

In the present work we investigated the factor responsible for the hæmagglutination-inhibiting activity of normal sera against the 'avid' Asian strains. The erythrocyte receptors were also studied. The spiral loop micro-technique described by one of us[9] was used in the hæmagglutination-inhibiting tests. The neutralization tests were performed in chorio-allantoic membrane cultures according to Horváth's method[10]. Fowl erythrocytes were used throughout.

Table 1 shows that none of the six animal species examined had serum inhibitors against the Singapore 1/57 strain, while all but the pooled mouse serum were highly inhibitory against Budapest 23/57, a representative of the 'avid' Asian strains. A sample of each of the sera listed in Table 1 had been boiled and vigorously stirred for 30 min., then centrifuged. The supernatants were tested. The hæmagglutination-inhibiting titres against the 'avid' strains were remarkably enhanced by boiling, while a nearly complete inactivation of the Francis and Chu inhib-

a, Active; *i*, inactivated at 56° C. for 30 min.
* Reciprocals of the hæmagglutination-inhibiting titres.

itors occurred as demonstrated by the disappearance of the hæmagglutination-inhibiting titres against active and heat-inactivated *PR*8 and Lee viruses. Boiled guinea pig sera had particularly high titres. The lowest temperature rendering sera more inhibitory against the 'avid' strains was dependent on the species; for example, heating to 56° C. for 30 min. was sufficient for guinea pig sera to develop higher hæmagglutination-inhibiting titres while sera of other species required considerably higher temperatures to become more effective. The 'non-avid' Singapore strain was not inhibited even by boiled sera.

Heating to 56° C. for 30 min. rendered *PR*8 and Lee virus preparations more sensitive to non-specific serum inhibitors but did not alter, or even lowered, the sensitivity of the 'avid' strains.

We have investigated some properties of the boiled inhibitor. It has been proved to be undialysable and biuret-positive; it is precipitated by 50 per cent acetone or 66 per cent ethanol; the precipitates can be re-dissolved without any loss in their inhibitory activity in saline; the inhibitor is completely precipitated in 0·35 saturated solutions of ammonium sulphate; digestion at 37° C. in a 0·25 per cent trypsin solution for 30 min. destroys its activity. Treatment of sera with crude cholera filtrate inactivated this inhibitor only partially and the Francis-type inhibitor had disappeared completely. Treatment with *M*/200 potassium periodate at room temperature for 3 hr. scarcely diminished the hæmagglutination-inhibiting titres of normal sera to the 'avid' strains, whereas those to the active and heat-inactivated preparations of *PR*8 and Lee viruses disappeared almost entirely. No carbohydrate could be detected in preparations purified by fractional precipitation with ammonium sulphate. The Molisch–Udránszky and the Antron tests were used.

Pre-epidemic human sera, as well as normal guinea pig sera, had also neutralizing titres against the 'avid' strains but not to the 'non-avid' Asian strains. The titres against 100 *ID*50 of an 'avid' strain attained 1 : 32 in pre-epidemic human and exceeded this level in normal guinea pig sera. Preliminary observations appear to suggest a direct relation between the hæmagglutination-inhibiting and neutralizing titres of normal sera. In a single experiment, however, boiling remarkably diminished the neutralizing capacity, in contrast to the simultaneous rise in the hæmagglutination-inhibiting titre.

Our results indicate that the 'avid' Asian strains are inhibited, and, to some extent neutralized, by a normal serum factor which is different from the non-specific inhibitors of hæmagglutination already described. The new inhibitor is supposed to be a thermostable protein or polypeptide.

The existence of a serum inhibitor reacting exclusively with the 'avid' Asian strains made reasonable a search for erythrocyte receptors supposed to be specific for those strains. The possible destruction of the receptors to the 'avid' strains by each of the strains *PR*8, Lee and Singapore 1/57 was examined first. Mixtures of virus and red cells were kept at 37° C. until the cells had become inagglutinable or barely agglutinable by all the strains tested except the 'avid' strains. The agglutinability by the latter was not altered by the above treatment. In further experiments red cells were treated with 'avid' strains in a similar manner. In these instances the rate of elution was slow, as compared with that of the 'non-avid' strains, and the red cells remained agglutinated even after extremely long incubation. We failed thus to obtain cell suspensions suitable for re-agglutination tests.

The effects of receptor-destroying enzyme as well as of potassium periodate on the red cell receptors reacting with the 'avid' strains were also studied. Using each of these treatments appropriately, we succeeded in obtaining cells of unaltered agglutinability by 'avid' strains but entirely inagglutinable by other strains of influenza virus.

Our preliminary results suggest that a receptor substance different from the red cell receptors to other strains of influenza virus is at least one of the substances responsible for the interactions between red cells and 'avid' strains of Asian virus.

We thank Dr. A. Isaacs, National Institute for Medical Research, London, for making available the Singapore 1/57 strain and crude filtrate of *V. cholerae*. A full account of this work will be published in the *Acta Virologica* (Prague).

Effect of Brain Ganglioside on the Heart of the Clam

A PURIFIED preparation of brain ganglioside, a macromolecular glycolipid the structure of which has been recently considerably clarified[1], has been shown to inhibit in low concentration the viral hæmagglutination reaction[2] and to inhibit in the same concentrations the neurotoxic effect in mouse brain of influenza *PR*8 and *NWS* viruses[3]. The consideration of the possible membrane and transport role that brain ganglioside might have in the central nervous system has led to the investigation of the effect of this substance upon the heart of *Venus mercenaria* (clam), an organ which had been used in the bioassay of acetyl choline, 5-hydroxytryptamine, and other substances with known or suspected neurohumoral function[4,5].

The clam heart system employed was essentially that described elsewhere[5], with the exception that a 5-ml. bath was used. (We are grateful to Dr. M. K. Paasonen for demonstrating the method which he employs for bioassay with clam heart, and for a sample of 5-hydroxytryptamine creatine sulphate.) The bathing fluid consisted of sea water, with and without added benzoquinonium ('Mytolon'). Most preparations functioned well up to 10 and 15 hr., and stable function was established for at least 1 hr. before test substances were added. All hearts were highly responsive to 5-hydroxytryptamine creatine sulphate in the usual doses[5].

Both brain ganglioside salt and its ash-free derivative were employed[1]. Brain ganglioside salt in concentrations as low as 0·06 μgm./c.c. of suspension fluid produced a definite increase in the amplitude of contraction (12–30 per cent). At doses greater than 0·4 μgm./c.c. an increase in amplitude of contraction was accompanied by an increase in rate as well. At doses between 40 and 200 μgm./c.c. an increase in tonus also occurred, with definite raising of the baseline. At doses between 200 and 400 μgm./c.c. a tetanic state of contraction was observed. All the above effects were readily reversed by washing the heart with sea water. However, there appeared to be a cumulative effect in individual hearts on repeated administration of large doses of brain ganglioside, evidenced by a diminished responsivity to subsequent doses of brain ganglioside, although the heart retained normal responsivity to 5-hydroxytryptamine. Even while the heart was responding to brain ganglioside present in the bathing fluid, the addition of 5-hydroxytryptamine produced a superimposed stimulatory effect.

All these responses were observed whether or not benzoquinonium (6 μgm./c.c.) was present in the fluid. Since equivalent responses were obtained with both brain ganglioside salt, and ash-free brain ganglioside, the stimulatory effect does not appear to be dependent upon either the presence of a free or neutralized carboxyl group in the neuraminic acid of brain ganglioside. Neuraminic acid itself, obtained by hydrolytic cleavage of ash-free brain ganglioside[1], in doses of 60–120 μgm./c.c., produced a small increase in the amplitude of contraction comparable to the response obtained with only 0·06 μgm./c.c. of the intact brain ganglioside.

The active concentrations of brain ganglioside are low. Considering that the functional unit of this macromolecular substance is its structural repeating unit, molecular weight[1] approximately 3,314, then brain ganglioside is active in this system at concentrations of 10^{-8} molar. If, on the other hand, the functional unit is considered to be that indicated by the molecular weight determination of aqueous brain ganglioside (minimal molecular weight 250,000), then brain ganglioside is active at concentrations of 10^{-10} molar.

These findings, which will be described in detail elsewhere, together with the previous observations on the structure of brain ganglioside[1] and on its action in other biological systems[2,3], suggest the possibility that brain ganglioside may play a part in transmission phenomena in the central nervous system.

These studies have been supported in part by grants from the U.S. National Institutes of Health (*M*-2095 and *B*-1616).

Succinic Dehydrogenase Activity in Brain Tissue of Rats after Ovariectomy and Steroid Administration

ANÆSTHETIC properties of certain steroids have been demonstrated by Selye[1], and Michaelis and Quastel[2] have stated that anæsthetic activity depends on inhibition of the utilization of glucose and oxygen by brain tissue. Later, Gordan and Elliott[3] showed that addition of certain steroids to brain cells *in vitro* produced a prompt inhibition of the rate of uptake of oxygen by these cells. Conversely, in castrated male rats, that is, in animals deficient in gonadal steroids, the uptake of oxygen by the brain increased up to 35 per cent[4,5]—a fact which suggests that the steroids, by virtue of their inhibiting effects, act as brakes on cerebral metabolism. Further experiments indicated that the known anæsthetic potency of the steroids parallels their degree of inhibition[6]. The site of the steroid inhibition has since been found to be at the dehydrogenase-level rather[7,8] than the cytochromes, where other anæsthetic agents exert their effects. Thus, the distinctive effects of steroids on the respiratory metabolism of tissues can be ascertained by means of the quantitative analysis of the dehydrogenase activity under conditions of steroid administration or deficiency.

Scrutiny of the literature revealed that the results obtained on the influence of steroids on the oxygen uptake and respiratory enzyme activity were based upon experiments on male rats exclusively. In our previous experiments the activity of succinic and isocitric dehydrogenases in brain and other tissues under various experimental conditions were determined in male rats also[9].

Therefore, in the present experiments female rats were used and the succinic dehydrogenase activity of brain tissue under the conditions of ovariectomy and administration of gonadal hormones was assayed.

Seventy adult healthy female rats of the random-bred Hebrew University strain were spayed at the age of 2 months and divided into four groups. 15 animals were injected with 1 mgm. testosterone, 15 with 5 μgm. of œstradiol-benzoate and 15 with 1 mgm. of progesterone, whereas 25 ovariectomized rats received no injections. An additional group of 24 normal animals served as a standard of comparison. The injections were given for a period of 30 days and were discontinued 24 hr. prior to the examination. The dehydrogenase activity was quantitatively estimated by a modification of the Kun and Abood[10] tetrazolium method, developed in our laboratory[11]. The method is based on the degree of reduction of tetrazolium to the end-product, formazan, during the enzymic oxidation of succinate to fumarate and is estimated colorimetrically.

The modification is as follows. The incubation mixture contains 0·5 ml. of a 10 per cent tissue homogenate in potassium phosphate buffer, 0·25 ml. of a 0·08 *M* solution of sodium succinate substrate and 0·25 ml. of a 0·1 per cent solution of neo-tetrazolium chloride, at 37° C. for 20 min. By the addition of 2 ml. of a mixture of equal parts of ethyl acetate–ethanol, the reaction is stopped and the coloured end-product, formazan, is extracted. Thus the colour of the formazan solution is rendered stable for a relatively long period, and the reaction is suitable for estimating small quantities of enzymes —the modified procedure eliminating thereby the main drawbacks of the original method.

It can be seen from Table 1 that after ovariectomy the succinic dehydrogenase activity in brain tissue increased markedly. The different gonadal hormones administered exerted a distinctive influence on the succinic dehydrogenase activity of the brain in ovariectomized rats. All three steroids inhibited in a statistically significant degree (after ovariectomy) the elevated enzyme activity. Testosterone decreased this activity to the greatest extent, depressing it relatively far beneath the normal level; œstradiol effected a marked decrease from the normal degree, whereas progesterone, although exerting an inhibiting effect, levelled the enzyme activity to the normal values only.

Table 1. EFFECTS OF OVARIECTOMIZED AND GONADAL STEROIDS ON CEREBRAL SUCCINIC DEHYDROGENASE ACTIVITY

The figures express the amount of formazan (μgm.) produced by the enzyme during 20 min. of incubation at 37° C. in 1 ml. of 10 per cent tissue homogenate

Treatment	No. of animals	Age in months	Mean ± S.E.	Alteration (per cent)	*t*	*P*
Intact, female	24	3	526±18	—	—	—
Ovariectomized	25	3	623±27	+18·4	3·03	0·001
Ovariectomized+testosterone	15	3	329±48	−37·4	3·78	0·001
Ovariectomized+œstrogen	15	3	472±11	−10·2	2·57	0·02
Ovariectomized+progesterone	15	3	526±25	0	2·62*	0·02*
Intact, male	10	3	434±26	—	—	—

* These figures were calculated in relation to those of the ovariectomized, all the rest to the intact, animal.

In comparison with normal male rats of corresponding age the values for activity of succinic dehydrogenase in brain tissue of the intact female are somewhat higher. However, the increase of activity of succinic dehydrogenase after ovariectomy is similar to that observed in male rats after castration; the action of œstrogen as inhibiting the enzyme activity also corresponds to its effects in male. Contrary to these, the effect of testosterone is inhibitory in the female, while in the male this hormone increased still further the enzyme activity already elevated after castration[9].

Since corresponding effects of progesterone and testosterone in many instances, including anæsthetic actions, are known, the results obtained with progesterone administration were rather unexpected. In the present experiments this hormone was the least effective in decreasing the enzyme activity, in contrast to testosterone, which inhibited it to the greatest extent.

A full account of the experiments will be published elsewhere.

We are indebted to Mrs. J. Kidron for technical help.

BIOLOGY

'Pheromones': a New Term for a Class of Biologically Active Substances

DURING the past few decades, investigations have been made into various active substances which, though they resemble hormones in some respects, cannot be included among them. For example, the sexual attractants of butterflies are, like hormones, produced and secreted by special glands; minute amounts cause a specific reaction in the receptor organ (the antenna of the male), which eventually leads to a state of copulative readiness. Unlike hormones, however, the substance is not secreted into the blood but outside the body; it does not serve humoral correlation within the organism but communication between individuals.

Referring to Starling's original definition, Bethe[1] called such substances 'ectohormones'; the name has been used by some authors but rejected by others. The most common definition of hormones to-day is that they are the products of endocrine glands. This should not be lightly expanded and diluted; in fact, it would be preferable to create and define a new term.

We propose, therefore, the designation 'pheromone' for this group of active substances. The name is derived from the Greek *pherein*, to transfer; *hormōn*, to excite. Pheromones are defined as substances which are secreted to the outside by an individual and received by a second individual of the same species, in which they release a specific reaction, for example, a definite behaviour or a developmental process. The principle of minute amounts being effective holds. The pheromones, messenger substances between individuals, thus take their place as a group beside the hormones, the gamones and the termones. Having stated that pheromones act on individuals of the same species, they must be differentiated from other stimulating substances, like phagostimulants, scents of flowers and insect repellents, which Bethe included among the ectohormones. Incidentally, strict species-specific activity is not required; certain overlaps between closely related species may occur.

There are various ways in which the recipient organism can detect pheromones. In a review shortly to be published, olfactory pheromones are distinguished from orally acting ones. The former, which can act over considerable distances, are perceived by chemoreceptors, from which nervous stimuli are sent to the central nervous system. If this released a certain behaviour, ethologists would place the pheromone concerned into the category of 'release stimuli'. The introduction of the term has been criticized for that reason (Verheijen-Voogd, C., personal communication). We nevertheless, on biological and biochemical grounds, regard it as sensible to mark off the pheromones from other chemical stimuli like food odours and others, and from optical, acoustic and similar releasers, as special messenger substances. It seems to us a fundamental difference whether an organism reacts to certain stimuli of the environment or creates for itself a means of communication of this kind. A clear definition of the pheromones and their specific action in particular cases should be of importance both to biochemical and to ecological research.

Among the active substances comprising the pheromones, most research has been carried out on those found in insects[2]. The queen substance of bees[3] and that of termites[4] inform the colony about the presence of the queen; if they are lacking, certain behaviour patterns and ovary development in the workers result. They act through the mouth, as do the active substances of the functional reproductives of termites, which inhibit the production of supplementary reproductives[5]. Should the hypothesis be confirmed, that royal jelly contains a specific developmental substance, formed in the lateral pharyngeal glands of the nurses, this, too, would be a pheromone. It is scarcely surprising that in the social insects in particular many pheromones are found, for these materials serve the social life of these animals.

The sexual attractants of butterflies and moths[6,7], cockroaches[8] and other insects, as well as the recognition odours of Hymenoptera[9,10], act through the olfactory sense. Lastly, the following substances also appear to fall into the category of pheromones: the sexual attractants of the Crustacea[11], the warning substance of the minnow[12], and probably also the territory-marking substances of the Carnivora, though here much remains to be solved.

The action of pheromones taken up orally can occur in two different ways. First, they can be perceived by the gustatory sense, thus making them absolutely analogous to the group of 'olfactory pheromones'. Apparently, the queen substance acts in this way (Butler, C. G., private communication). Secondly, there is the possibility that they may be resorbed in the digestive tract and develop their specific action by diffusing into the blood. This mode of action has not been proved in any special case. Therefore, we regard it as not yet expedient, or at least premature, to split the concept or make two definitions (for example, 'pheromones' acting through the senses and 'telemones' acting through the blood system). Chemoreception (basically a biochemical effect, too) and action of a hormone need not be contradictory; there are numerous examples of sensory stimuli or psychological excitations causing hormone secretion and of hormones releasing psychological states or behaviour patterns (nest building, parental behaviour). Finally, it is not easy to distinguish experimentally between sensory and biochemical effects, and therefore a clear classification is often just not possible.

The definition of pheromones has been discussed with several colleagues working in the field, and has found approval by A. Butenandt, Munich; C. G. Butler, Rothamsted; D. B. Carlisle, Plymouth; R. Chauvin, Burs-sur-Yvette; P. T. Haskell, London; B. Kullenberg, Uppsala; D. Schneider, Munich; R. Stumper, Luxemburg. We therefore throw the definition given above open for discussion and hope that it will prove itself in practice.

Carotenoid Pigment in *Spirobacillus cienkowskii* Metchnikoff, a Pathogen of Cladocera

Cladocera are often coloured red by hæmoglobin in their blood[1]; another red pigment has been found in specimens infected by *Spirobacillus cienkowskii* which Metchnikoff[2] described from *Daphnia magna* Straus. The bacterium passes through a series of stages within the cladoceran and causes it to assume a bright red colour.

As a general rule less than 1 per cent of a cladoceran population shows signs of infection, but I have recently found a population of *Simocephalus vetulus* O. F. Müller in which up to 2 per cent of the individuals were infected. Several specimens of *Sida crystallina* (O. F. Müller) from the same body of water were also found to be infected with the same bacterium.

About three hundred infected specimens of *Simocephalus* were ground up in water and then centrifuged

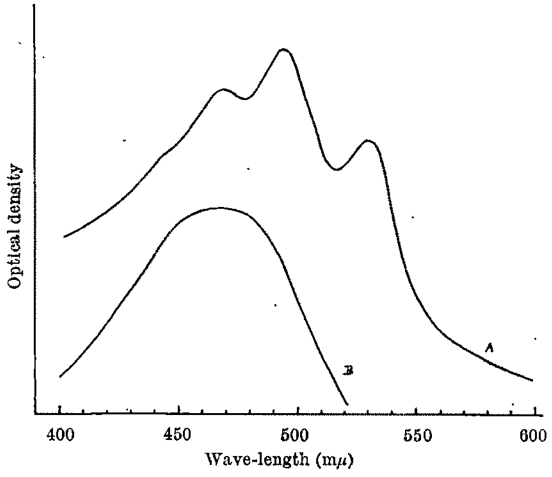

Fig. 1

at low speeds to leave a cloudy red suspension which consisted almost entirely of bacteria. When this suspension was centrifuged at 9,000 r.p.m. the bacteria were all spun down and a colourless fluid was left. This demonstrates that the pigment is confined to the bodies of the bacteria and is not a host reaction. The bacterial sludge was treated with acetone, when the pigment was easily extracted, then taken into petrol ether (boiling point, 60–80° C.) after dilution of the acetone with water. The solution in petrol ether was dried over anhydrous sodium sulphate and examined in a spectrophotometer. Absorption peaks were found at 470, 495 and 530 mμ (Fig. 1,*A*). The last two peaks are in fair agreement with those of rhodoviolascin and those of α-bacteriopurpurin, which is probably a demethylated form of rhodoviolascin[3]. The first peak is about 10 mμ too far towards the red end of the spectrum. The explanation for this was found when uninfected specimens of *Simocephalus* were treated in the same way as the infected specimens. An olive-green supernatant fluid was left after centrifuging; when this was treated with acetone it turned orange. The orange pigment was taken into petrol ether after dilution of the acetone water phase with more water. The absorption curve of the petrol ether solution is shown in Fig. 1,*B*. The single peak at 470 mμ agrees with that of astacene derived from astaxanthin which was present in the form of a green carotenoprotein. The presence of a small amount of astacene in the extract from the infected specimens would account for the apparent bathochromic displacement of the first peak of the bacterial pigment.

It is evident from these observations that the red pigment is a carotenoid of the α-bacteriopurpurin type, and that it is confined to the bacteria. There is an indication that the pigment is at least partially derived from carotenoid present in the host, because the patches of carotenoid protein which normally occur in healthy *Simocephalus* are changed to red when the pigment-bearing cells are infected with the bacterium.

Adaptive Synthesis of Nitrate Reductase in Higher Plants

ADAPTIVE production of enzymes in higher plants is not widely recognized, although two examples have been reported[1]. Nitrate reductase systems are adaptive to nitrate and nitrite in micro-organisms[2,3] and studies with cauliflower[4] have suggested a similar adaptive character in higher plants. Tang and Wu[5] obtained more direct evidence of the adaptive character of this enzyme in rice seedlings germinated for five days under sterile conditions and Rijven[6] reported similar results for wheat embryos germinated for 24 hr. These experiments, however, involved relatively prolonged periods of contact between inducer and tissues undergoing both rapid cell division and expansion.

We have found in numerous tests that production of nitrate reductase activity can be rapidly induced in small fragments of leaves excised from cauliflower (*Brassica oleracea* var. *botrytis*), white mustard (*Sinapis alba*) and sunflower (*Helianthus annuus*). Fig. 1 shows results of experiments in which nitrate or molybdenum, or both, were introduced, by vacuum infiltration, into excised fragments of partially or fully expanded leaves of cauliflower grown in sand culture with ammonium sulphate or nitrate each with or without molybdenum. Rapid production of enzyme activity occurred on the introduction of nitrate into leaf tissues grown with ammonium sulphate, often apparently after a lag-period of about 1 hr. The introduction of molybdenum into leaves of plants deficient in molybdenum and grown with nitrate had a similar effect, resembling that observed in fungi[3]. Tissues of plants grown with ammonium sulphate but without molybdenum responded little or not at all to either factor alone, but rapidly developed activity when both were present.

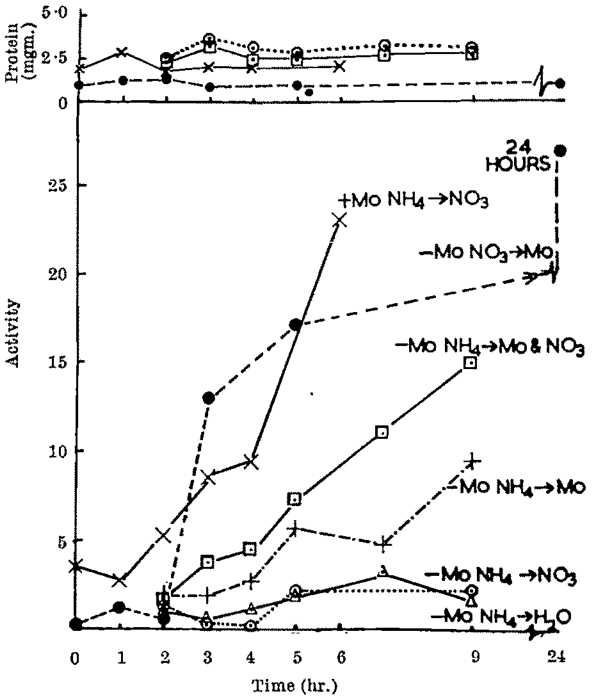

Fig. 1. Effect of infiltration with water, molybdenum, nitrate and molybdenum plus nitrate on the development of nitrate reductase activity (mμmole NO_2/15 min./mgm. protein) in excised leaf fragments of cauliflower grown with different nitrogen and molybdenum supplies. Mo at 5 μgm./ml. and NO_3 at 2·48 mgm./ml. in infiltrating solution

The increases in enzyme activity greatly exceed corresponding changes, if any, observed in soluble protein content. The conclusion that protein synthesis is involved in the production of enzyme activity is supported, however, from studies with antimetabolites, some of which are known to inhibit protein synthesis. Table 1 shows results for cauliflower and mustard obtained with actidione, 1 : 2-dichloro-4-(*p*-nitrobenzenesulphonylamido)-5-nitrobenzene (DCDNS) and polymyxin *B*-sulphate introduced simultaneously with the other factors. From the concentrations ranging between 20 and 300 μgm./ml. of inhibitors in the infiltrating solutions, we tentatively estimate that the concentrations resulting in the cells were of the order of 5×10^{-6} *M* for actidione and 7×10^{-5} *M* for 1 : 2-dichloro-4-(*p*-nitrobenzenesulphonylamido)-5-nitrobenzene. Polymyxin was present at 2 mgm./ml. in the infiltrating solutions. All three antimetabolites markedly

Table 1. Effects of Antimetabolites as Inhibitors of the Synthesis of Nitrate Reductase in Excised Leaf Fragments

(1) Plant and nutrient treatment during growth		(2) Infiltration • medium	(3) Activity (mμM NO_2/15 min./mgm. protein) in extracts prepared 6–9 hr. after infiltration with medium shown, with (+) or without (−) inhibitor, or with water (O) but omitting activating treatments in column (2):								
			Actidione			DCDNS			Polymyxin *B*		
			+	−	O	+	−	O	+	−	O
Cauliflower	− Mo NO_3	Mo	6·5	27·8	2·5	19·7	30·2	1·5	12·2	83·2	0·0
Cauliflower	− Mo NH_4	Mo + NO_3	3·5	29·0	0·0						
Mustard	− Mo NH_4	Mo + NO_3	11·2	61·0	1·5	5·0	61·0	1·5			
Mustard	+ Mo Urea	NO_3	20·7	64·0	24·0	22·9	52·0	29·0	28·2	67·0	40·2

inhibited the synthesis of the enzyme in intact tissues that were no longer undergoing cell division but which were probably capable of further cell expansion. The inhibition applied apparently equally to the adaptive effect of nitrate and to the determining influence of molybdenum on enzyme formation. There was no inhibition of activity *in vitro*. The question of absolute adaptive response to nitrate or of increased production of a constitutive enzyme remains unsettled at this stage.

Other antimetabolites, including *p*-fluorophenylalanine, β-2-thienylalanine, chloramphenicol, 8-azaguanine, 2-thiouracil, 5-methyl-2-thiouricil, streptomycin, aureomycin, neomycin, gramicidin, bacitracin and tyrothrycin, did not, as tested, inhibit the response either to molybdenum or to molybdenum and nitrate together. Chloramphenicol and aureomycin may, however, inhibit protein synthesis less in cell-free preparations from plants[7] than from bacteria, and even bacteria may show varying tolerance to the effect of chloramphenicol on the adaptive synthesis of nitrate reductase[8].

The results in Fig. 2 suggest that nitrate reductase is relatively labile *in vivo* and may decrease in excised or attached leaves with time unless stabilized by the continued presence of the substrate. Other experiments have shown that infiltration with the inhibitory antimetabolites alone, of tissues already possessing activity, causes a further marked decrease in activity with time as compared with the effects of water as control. It is possible, therefore, that the enzyme is de-adaptive and that there is a rapid 'turn-over' in terms of simultaneous synthesis and breakdown. In the absence of a significant substrate concentration there would be a steady net decrease, greatly accentuated in the presence of an inhibitor of synthesis.

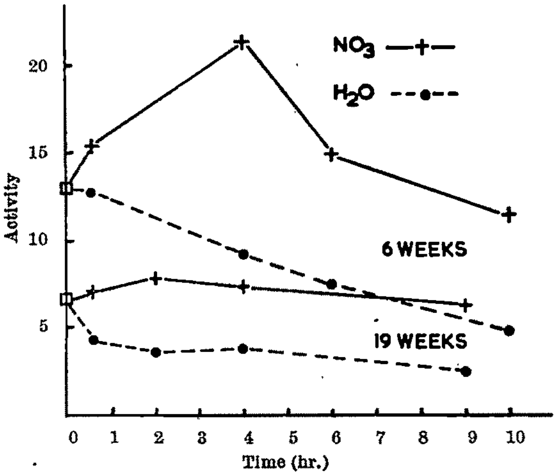

Fig. 2. Effect of infiltration with water or nitrate on the nitrate reductase activity (mμM NO_2/15 min./mgm. protein) of excised leaf fragments of cauliflower plants 6 weeks and 19 weeks old grown with molybdenum and nitrate. NO_3 at 2·48 mgm./ml. in infiltrating solution

The full details of this and continued investigations will be published elsewhere. We wish to thank Dr. D. W. Woolley of the Rockefeller Institute, New York, for a generous gift of 1 : 2-dichloro-4-(*p*-nitrobenzenesulphonylamido)-5-nitrobenzene. The award of a Colombo Plan Overseas Studentship to one of us (M. M. R. K. A.) is gratefully acknowledged.

Effects of Gibberellic Acid on Development of Autumn Colour and Leaf-fall of Deciduous Woody Plants

Gibberellic acid does not affect petiole abscission in *Coleus* explants[1], but we have found that treatment of some intact deciduous woody plants with gibberellic acid markedly influences development of autumn foliage colour and leaf-fall.

Gibberellic acid was applied as an aqueous spray (0·005 per cent gibberellic acid, 0·01 per cent 'Tween 20', 1·0 per cent glycerol) to all leaves of a selected branch on each plant; a comparable branch was sprayed with the inert constituents of the spray fluid, but on no occasion did this control treatment produce any observable effect as compared with unsprayed parts of the plant. The first application of spray was made on August 11, 1958, and thereafter at weekly intervals.

Little or no effect was noticed with *Acer rubrum* L., *Castanea sativa* Miller, *Fagus sylvatica* L., *Quercus robur* L., or *Ulmus procera* Salisb. Gibberellic acid delayed development of autumn colours and leaf-abscission in the following: *Acer pseudoplatanus* L., *Betula verrucosa* Ehrh., *Fraxinus excelsior* L., *Liriodendron tulipifera* L., *Parthenocissus tricuspidata* Planch., *Prunus avium* L .and a *Rhododendron* × *molle* cultivar. The most striking effects were noticed with *Fraxinus excelsior*, *Prunus avium* and *Acer pseudoplatanus*; all leaves were still quite green on November 21, whereas all leaves from untreated branches had fallen. Only slightly less striking was the effect on *Liriodendron tulipifera*; on November 21 nearly all treated leaves were still green, whereas all other leaves remaining on the tree were bright yellow.

In complete contrast, development of autumn colour and abscission of short shoots and leaves of *Taxodium distichum* Rich. was advanced by treatment with gibberellic acid. The leaves turned bronze in colour shortly after the first treatment, and all leaves on treated branches had fallen by October 20; whereas bronzing of leaves on untreated branches was only beginning at that date, and leaf-fall was only partial on November 21.

Shoot extension had ceased in most of these plants at the time of the first treatment. Lateral and apical buds resumed activity, and new shoots and leaves were formed as a result of treatment with gibberellic acid in *Acer pseudoplatanus*, *Betula verrucosa* and *Liriodendron tulipifera*.

Thus most species treated with gibberellic acid gave one or more of the following responses: delay in development of autumn foliage colour, delay of leaf-abscission, renewal of shoot growth. These are characteristic responses to long-day conditions[2,3], and this result affords one more example of the induction by gibberellins of typical long-day responses[4]. The anomalous result with *Taxodium distichum* awaits explanation.

Gibberellin Effects on Photoperiod-controlled Growth of *Weigela*

Weigela, a woody ornamental plant, produces uninterrupted vegetative extension when grown at photoperiods in excess of 14 hr., whereas at shorter photoperiods (<14 hr.) vegetative growth ceases, and the plant enters a dormant condition[1-3]. This communication describes the replacement of the photoperiodic requirement for the vegetative development of *Weigela* with gibberellin applied to plants grown under a short photoperiod, and the acceleration of growth under a long photoperiod.

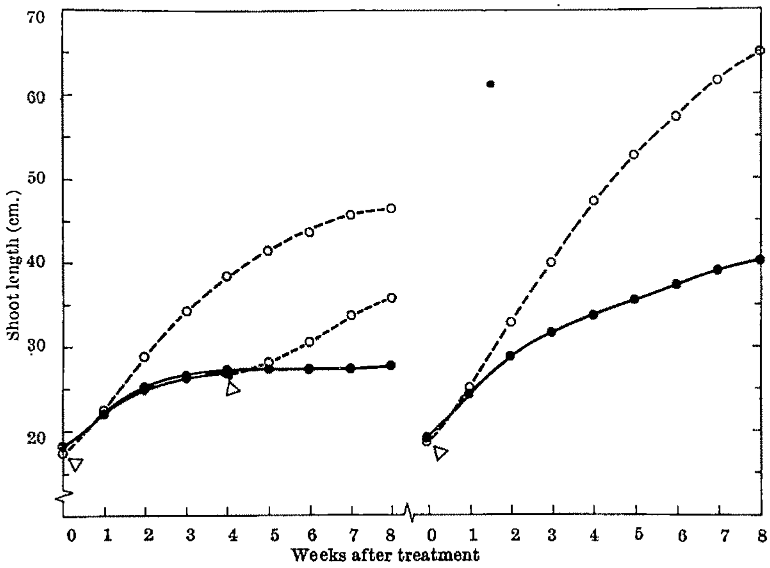

Fig. 1. Growth-rate curves illustrating the effect of gibberellin on the vegetative extension of *Weigela* cl. 'Vanicek' grown at 9-hr. (left) and 18-hr. (right) photoperiods. ○ - - - ○, treated with gibberellin; ●——●, untreated. △, Time of treatment with gibberellin

Two-year-old plants of *Weigela* cl. 'Vanicek' were grown in pot cultures in a greenhouse at an 18-hr. photoperiod and 16° C. night temperatures until growth-rates were well established (shoot elongation of 4·0 cm./week). Plants were selected for uniformity, pruned to five vegetative shoots, and six plants subjected to each of the following treatments: (*a*) retained at an 18-hr. photoperiod; (*b*) treated with gibberellin and retained at an 18-hr. photoperiod; (*c*) transferred to a 9-hr. photoperiod; (*d*) treated with gibberellin and transferred to a 9-hr. photoperiod; (*e*) transferred to a 9-hr. photoperiod and treated with gibberellin after dormancy was induced (4 weeks). Gibberellin treatment consisted of a single foliar spray of 50 p.p.m. (acid equivalent) of potassium gibberellate (potassium gibberellate was presented by Merck and Co., Inc., Rahway, N.J.) plus 0·1 per cent 'Tween 20' (polyoxyethylene sorbitan monolaurate supplied by courtesy of the Atlas Powder Co., Wilmington, Delaware) as a wetting agent. All plants were exposed to 9 hr. of natural daylight. Those under an 18-hr. photoperiod were exposed for an additional 9 hr. to artificial light (30 foot-candles from 60-watt incandescent-filament lamps).

A single foliar spray (50 p.p.m.) of gibberellin on *Weigela* subjected to the 9-hr. photoperiod resulted in continued shoot elongation during the course of the experiment. Comparable plants not treated with gibberellin ceased vegetative extension (Fig. 1, left), and formed rosettes after three weeks. Dormancy, induced by a short (9-hr.) photoperiod, was broken, and growth-rates in excess of those in non-treated plants grown at an 18-hr. photoperiod were established. After eight weeks the length of shoots on plants treated with gibberellin at the 9-hr. photoperiod exceeded that of the non-treated plants at the same photoperiod by 65 per cent. The growth of shoots of the treated plants in the short photoperiod (treatment *d*) compared favourably with, and even exceeded (by 15 per cent) those for the non-treated plants retained at the 18-hr. photoperiod (treatment *a*). Thus, the photoperiodic requirement for vegetative elongation and breaking the photo-induced dormancy was replaced with gibberellin. The effect of gibberellin, at the short photoperiod, began to diminish after 3 or 4 weeks as indicated by the decreasing growth-rate.

Gibberellin also promoted growth in *Weigela* at the 18-hr. photoperiod, and this increased rate of growth was maintained throughout the experiment (Fig. 1, right). Growth of shoots, eight weeks after gibberellin treatment, at the 18-hr. photoperiod, exceeded that of the non-treated plants by 63 per cent.

The gibberellin-promoted increase in shoot extension at the 18-hr. photoperiod was primarily attributed to an increase in length of internodes, while at the 9-hr. photoperiod both length and the number of nodes were increased.

Leaves on treated plants were generally longer, narrower, and paler green than those on non-treated plants at both photoperiods.

Gibberellin applied to *Weigela* plants grown under a 9-hr. photoperiod induced growth of shoots and broke the photo-induced dormancy, hitherto possible only with long photoperiods. Furthermore, gibberellin accelerated the rate of growth of *Weigela* when grown under a photoperiod conducive of continuous vegetative extension.

Interaction between Kinetin and Indoleacetic Acid in the Control of Bud Reactivation in *Splachnum ampullaceum* (L.) Hedw.

It has been shown[1] that the apical region of the gametophore of *Splachnum ampullaceum* (L.) Hedw. inhibits both lateral bud reactivation throughout the gametophore and protonematal regeneration from the base of the gametophore. These apical dominance effects could be replaced by the application of indoleacetic acid to the tips of decapitated plants.

Recently, Wickson and Thimann[2] presented evidence which indicates that apical dominance in *Pisum sativum* in terms of the inhibition of lateral bud reactivation is governed by an interaction of kinetin or kinetin-like factor and auxin.

The experiments described in the present communication were undertaken with the following questions in mind: (1) Is an interaction between kinetin and auxin similar to that found by Wickson and Thimann responsible for reactivation phenomena in the gametophore ? (2) If so, are the mechanisms of correlation inhibiting lateral bud reactivation and protonematal regeneration from the base of the gametophore identical or different for these apical dominance effects ? This question remained an open one in the investigation mentioned above[1].

The male strain of *Splachnum ampullaceum* was used. Plants were reproduced vegetatively and the gametophores treated were always 20–21 days old. They were grown on Beijerinck's inorganic solution plus 1 per cent agar. The *p*H of the medium was adjusted to 6·0. The plants were kept under continuous artificial illumination with fluorescent (daylight) lamps. The compounds tested were administered in small blocks containing 2 per cent agar placed on the tips of decapitated plants immediately following decapitation. Lateral bud reactivation and basal regeneration were examined four days after the beginning of the treatment. The blocks were changed twice per day over the four-day period. The amount of bud reactivation realized was taken as number of branches/number of axils × 100. The results are given in Table 1. Kinetin was obtained from the H. M. Chemical Co., Ltd., Santa Monica, California.

Table 1. LATERAL BUD REACTIVATION AND PROTONEMATAL REGENERATION FOUR DAYS AFTER THE BEGINNING OF TREATMENT

Treatment	Percentage of bud reactivation	Reactivation of basal bud*	Length of longest branch (mm.)	No. of protonemata
Intact	0	0	—	28
Decapitated + water	84	70	0·418	46
Decapitated + IAA (1 mgm./ml.)	0	0	—	31
Decapitated + K (1 mgm./ml.)	90	100	0·350	41
Decapitated + IAA (1 mgm./ml.) + K (1 mgm./ml.)	79	80	0·291	33
Decapitated + IAA (1 mgm./ml.) + K (1×10^{-1} mgm./ml.)	60	40	0·258	31
Decapitated + IAA (1 mgm./ml.) + K (1×10^{-2} mgm./ml.)	45	10	0·220	30
Decapitated + IAA (1 mgm./ml.) + K (1×10^{-3} mgm./ml.)	42	0	0·125	29

*Determined as number of most basal branches/10 plants × 100.

It may be seen from these results that the apical region inhibits lateral bud reactivation completely at this stage of gametophore development and that it has a depressing effect on the realization of regenerative potentialities at the base of the gametophore. Both these apical dominance effects can be replaced by the application of indoleacetic acid (IAA) at the given concentration to the tip of the decapitated gametophore. Kinetin (K) is seen to have a strong antagonistic effect on the action of indoleacetic acid in that it promotes lateral bud reactivation in the presence of indoleacetic acid. Kinetin does not seem to have any effect in counteracting the action of indoleacetic acid on basal regeneration.

These results indicate, therefore, that an interaction between kinetin and indoleacetic acid may control reactivation of lateral buds in the gametophore similar to the situation described by Wickson and Thimann for *Pisum sativum*. Since kinetin does not counteract the effect of the apex or indoleacetic acid on the depression of basal regeneration, it may be concluded that the mechanisms of correlation mediating apical dominance in terms of the inhibition of lateral bud reactivation and the depression of basal protonematal regeneration are not identical.

Since both kinetin and indoleacetic acid have to migrate from the tip of the decapitated plant to its base, the site of protonematal regeneration, it could be maintained that the failure of kinetin to counteract the effect of indoleacetic acid in this latter phenomenon may be due to differences in the translocation of these two compounds, for example, due to differences in inactivating principles. To test this possibility, the percentage of reactivation of the most basal bud was examined for the various treatments. The results are given in the second column of Table 1. They indicate that kinetin also antagonizes the inhibitory effect of indoleacetic acid on reactivation in the most basal bud. Since this bud is rather close to the base of the gametophore, the site of basal regeneration, it may be concluded that differences in translocation between the two compounds probably cannot be the basis for the ineffectiveness of kinetin in counteracting the inhibitory effect of indoleacetic acid on basal regeneration. Hence the mechanisms governing correlative inhibition of lateral bud reactivation and basal protonematal regeneration by the apical region of the gametophore appear to be different from each other.

It should be mentioned here that Gorton and Eakin[3] have investigated gametophore initiation in the protonemata (induction of "dauermodifikation"[4]) of *Tortella caespitosa*. Bud initiation was found here to be inhibited by high concentrations of auxin, and was strongly stimulated by kinetin. Kinetin reversed the inhibition of bud formation brought about by napthalene acetic acid. It seems, therefore, that certain stages in the induction of "dauermodifikation", that is, bud initiation in the protonemata, and lateral bud reactivation in the gametophore may be mediated by the same mechanism.

This study was supported by a grant from the National Research Council of Canada. Technical assistance by Miss Veronika Ruf is gratefully acknowledged.

Temperature and Symbiotic Nitrogen Fixation

Moderately high temperatures have been found to exert a specific inhibitory effect on symbiotic nitrogen fixation. The results of an experiment illustrating this effect are given in Table 1.

Table 1. Effect of Temperature, Inoculation with *Rhizobium*, and Potassium Nitrate on the Yield and Percentage Protein Nitrogen of Subterranean Clover (Means of Four Replicates)

Treatment	Yield of dry matter per tube (mgm.)		Protein nitrogen in plants (per cent)	
	20° C.	30° C.	20° C.	30° C.
Without nitrogen or *Rhizobium*	38·0	35·2	1·35	1·54
Inoculated with *Rhizobium*	54·5	35·3*	2·66	1·69*
With potassium nitrate	56·8	62·0	2·59	2·55
Standard error expressed as percentage of mean	4·9 per cent		4·3 per cent	

* Interaction between form of nitrogen (*Rhizobium* v. potassium nitrate) and temperature is significant at $P < 0{\cdot}001$ for both yield and percentage protein nitrogen.

For this experiment, subterranean clover (*Trifolium subterraneum* L. var. Bacchus Marsh) plants were grown on nitrogen-free nutrient agar in test-tubes which were stood in temperature-controlled water-baths in a glasshouse. The results show that the uninoculated plants responded normally to nitrogen treatment at both temperatures. By contrast, plants inoculated with *Rhizobium* fixed nitrogen and grew normally only at the lower temperature. The inoculated plants were well nodulated at both temperatures. Thus the symbiotic nitrogen fixation process was specifically inhibited at the higher temperature.

We have investigated the hypothesis that this inhibitory effect of high temperature is due to a decrease in the supply of soluble carbohydrate to the nodule, resulting from an increase in the rate of respiration. The addition of sucrose to the culture medium in aseptic cultures did not increase the amount of nitrogen fixed at either the high or low temperature. The sucrose increased the yield of the plants but decreased the percentage nitrogen, indicating that the added sucrose was taken up by the plants but was not required directly for nitrogen fixation. We have therefore begun to examine the possibility that the high temperature has induced the deficiency of some other metabolite essential for symbiotic nitrogen fixation.

These findings also raise a number of other interesting problems. One of these concerns the reported harmful effects of high light intensity on symbiotic nitrogen fixation. This was first reported as long ago as 1935[1,2], when shading was shown to have a remarkable effect in breaking the nitrogen-hunger period in legumes. This response to shading was interpreted in terms of an effect on light intensity and photosynthesis. In our experiments we have been able to obtain marked responses and apparently normal growth of clover under the conditions of high light intensity of our summer by cooling the plants. It would appear that there is a need to determine in greater detail the relative effects of high temperature and high light intensity on symbiotic nitrogen fixation.

The significance of these findings in relation to the culture of legumes under experimental and field conditions is also an important matter for investigation. We have evidence that these effects are of importance in the culture of legumes in glasshouses in warmer weather, not only where the plants are grown in test-tubes, but also for larger pots. In fact the present work arose from observations made during the course of a pot culture experiment conducted during 1957, when it was found that subterranean clover grown in soil in pots made of clear polystyrene plastic were stunted and pale green in comparison with the larger dark green plants in corresponding enamelled pots. The reason for this difference was traced to the considerably higher soil temperature in the clear plastic pots. Since becoming aware of this effect we have obtained unmistakable evidence of suboptimal symbiotic nitrogen fixation in clover grown in various kinds of pots where soil temperatures have exceeded about 25° C.

We have no direct evidence on the possible effects of high temperatures on symbiotic nitrogen fixation under field conditions. In view of the temperatures involved it would seem that such effects may be of significance, particularly under irrigation in the warmer months, or in tropical and sub-tropical environments.

Full details of the experiments that have been done on this problem will be published elsewhere.

Electrophoretic Patterns of Mealworm Proteins

THE literature concerning insect proteins is, generally, represented by analyses of single developmental stages, usually immature, hæmolymph being the principal fluid investigated. The results of these studies show that the protein component fluctuates during development[1-4]. This communication shows the variations for the protein component of the mealworm *Tenebrio molitor*, during its developmental stages. The method employed, electrophoresis, seems to be a useful facility for investigations of this nature, since electrophoretic patterns of proteins are distinctive. Specific pattern characteristics have been reported for developmental stages of mammals[5], closely related species of reptiles[6,7], and amphibians[8,9].

The insects were raised in the laboratory on a diet of chicken mash and grain and a daily ration of water. Eggs, laid in white flour, were harvested daily, and white larvæ, pupæ and adults were collected within one hour following their emergence. In this manner timed records were maintained for each phase of the life-cycle. Approximately 100 mgm. of eggs, newly emerged and 14-day-old larvæ were separately homogenized in 1 ml. of water in a tissue homogenizer. The posterior abdominal segment of pupæ and adults was severed and the body contents extruded into separate weighing vials containing 1 ml. of water until 100 mgm. had been collected. The samples were centrifuged and the supernates retained for electrophoresis. 0·02-ml. volumes of extract were applied to Whatman No. 1 filter paper strips for analysis ('Spinco' electrophoretic system, barbital buffer *p*H 8·6, ionic strength 0·05, 5 m.amp., 16 hr.). The strips were dried at 120° C. for 30 min., stained with light green *SF*[10] and scanned with a recording densitometer ('Spinco Analytrol').

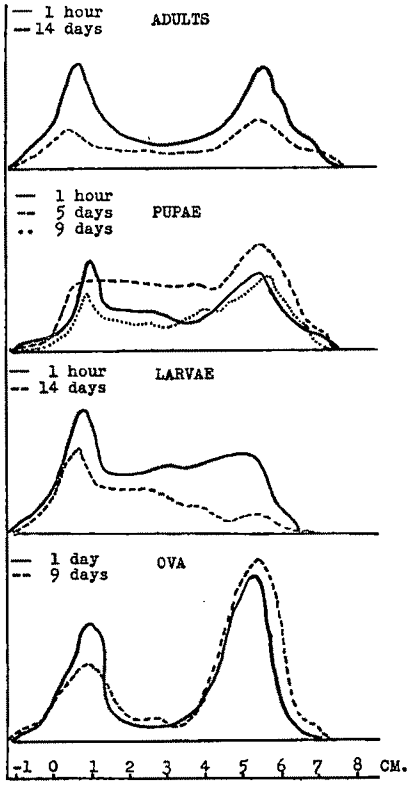

Fig. 1. Paper electrophoresis patterns of the mealworm *Tenebrio molitor*, at various stages of development. Extract, 0·02 ml., was applied at 0 cm.; anode is to the right

The electrophoretic patterns in Fig. 1 show two distinct anodal fractions for all stages except[7] the 14-day-old larvæ. The slower migrating fraction shows a well-defined band between −1 and 1 cm. from the point of origin. The faster fraction is well resolved between 4 and 6 cm. from the point of origin.

A comparison of the four stages discloses a uniformity in pattern for the slow fraction. Its concentration decreased as each phase of the developing mealworm progressed towards maturity. The fast fraction patterns are more variable. The peak is greater than that of the slow fraction for the egg and 5-day-old pupæ, approximately equal for the adults and the 9-day-old pupæ, and lower for the remaining groups. The eggs and pupæ also show alternation of the high peaks for the two fractions during their respective growth periods. A similar pattern prevails for the 1-hr. and 5-day-old pupæ. The trough separating the two peaks is relatively low for the ova and adults. The mid-pattern of the pupæ depicts a distinct rise and fall in concentration with increasing age.

These results show, generally, the direction of change for each stage of development and suggest the influence of basic growth activities. The results display the same type of variation as do morphological and physiological factors in bringing about protein changes in response to a modification of immature tissues for the subsequent building of the mature structure.

This study suggests the value of paper electrophoresis in revealing characteristics of insect proteins for investigating the comparative physiology of life-cycle activities.

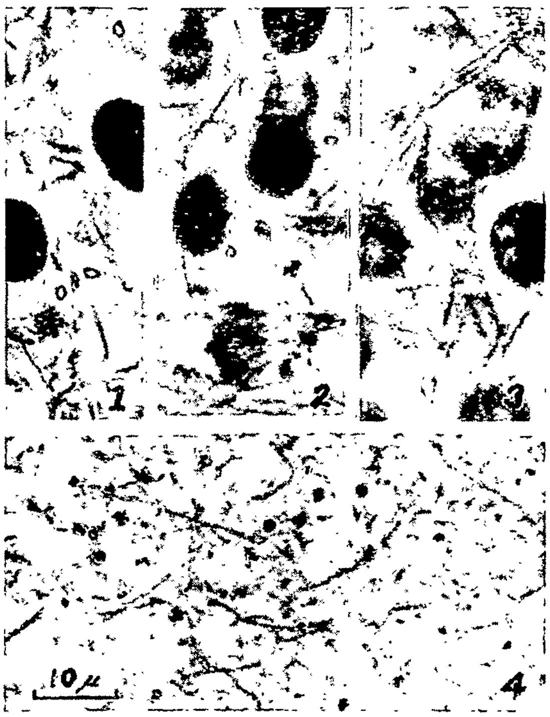
Environmental Temperature and the Reptilian Nervous System

IT has been found that the terminal plexus of the reptilian brain undergoes marked changes with the environmental temperature.

Lizards (*Lacerta viridis*) have been kept at 19° C. and at 32 ± 3° C. for periods up to 8 weeks. Some of the animals (twenty-four) were killed by perfusion with saline followed by 10 per cent neutralized formol saline under ether or urethane anæsthesia, and the brains were prepared by the Holmes method. Other



Figs. 1 and 2. The large-celled layer of the hippocampus. Animal kept at 19° C.

Fig. 3. The large-celled layer of the hippocampus. Animal kept at 32° C.

Fig. 4. The nucleus sphæricus. Animal kept at 32° C. All figures taken from Holmes's preparations at the same magnification

animals (five) were decapitated under ether anæsthesia and the brains prepared by the Nonidez technique. Observations have been confined to the large-celled layer of the hippocampus, the nucleus sphæricus (posterior hypopallium) and the nuclei of the seventh and eighth cranial nerves.

Lizards that had been kept at 19° C. for 8 weeks showed a large number of well-stained terminal rings and a few swollen fibres distributed among the cells of the large-celled layer of the hippocampus and in the cranial nerve nuclei (Figs. 1 and 2). The fine-fibre plexus of the nucleus sphæricus showed irregular staining suggestive of degenerative changes.

Animals that had been kept at 32 ± 3° C. showed relatively few rings in any of the cell groups investigated (Fig. 3). In the nucleus sphæricus a number of solid blobs 1–3μ in diameter appeared in the irregularly stained fibre plexus (Fig. 4). These blobs only appeared after the animals had been kept at 32° C. for about three weeks. They continued to increase in size and number up to eight weeks.

Lizards obtained fresh from the dealers showed the typical cold picture in some groups of animals and an intermediate picture in others.

These differences are independent of the anæsthetic or the method of preparation. It is probable that they are related to the neurofibrillar thickening that Tello[1] and Cajal[2] found in hibernating reptiles.

The changes that have been found may give further information about the nature of the finer terminals. Some of the appearances of rings, swollen fibres and blobs are suggestive of degeneration in fine terminal ramifications and could be mistaken for degeneration products of experimental lesions.

We wish to thank Miss B. Shirra for the histological preparations and Mr. J. Armstrong for the photographs.

A Hepatotoxin from *Sporidesmium bakeri* capable of producing Facial Eczema Diseases in Sheep

A PREVIOUS communication[1] reported that spores of a fungus identified as *Sporidesmium bakeri* Syd. contained the 'beaker test' substance found to be associated with toxicity of pasture samples on which the disease known as facial eczema had occurred.

In initial experiments mycelial felts grown on Raulin–Thom and Czapek–Dox media failed to produce liver lesions when fed to guinea pigs. The material so fed was also negative to the 'beaker test'. Subsequent experiments with a high-sporing strain of the fungus, grown on potato–carrot extract medium, produced liver damage in guinea pigs, indistinguishable from that obtained after feeding hepatotoxic grass. The material fed comprised a mixture of mycelial felts, spores and medium. Similar fungal material produced liver lesions characteristic of facial eczema in lambs. Later a clinical case showing typical icterus and photosensitization was produced.

The specific nature of the liver lesions was diagnosed in both guinea pigs and lambs by D. C. Dodd, of Ruakura. The assistance is acknowledged of D. J. Ross of the Soil Bureau and W. Crawley of Ruakura in cultural methods and E. P. White of Ruakura in chemical work.

Experiments are being planned to determine whether the hepatotoxin of this fungus is also responsible for facial eczema as it occurs in the field.

A Bacterium with Fungicidal Activity

IN a recent communication, Percival and Thornton[1] referred to the relationship between fungal spores and a test for hepatotoxic grass. It has since been shown that the fungus is *Sporidesmium bakeri* Syd. and is the source of the hepatotoxin which causes the specific liver damage which occurs in the disease known as 'facial eczema'. In connexion with this work, we have isolated a strain of *B. subtilis* which has a marked inhibitory effect on the growth of this fungus on culture media. Further investigations are being carried out to determine its spectrum of antibiotic activity and its relationship to the fungus in the field.

Rutin in Tobacco grown in a Greenhouse

IT has been reported[1-3] that leaf from tobacco grown in a greenhouse contains no rutin and in general much less polyphenolic material than leaf from plants grown in the field, and it has been concluded that the filtering action of the greenhouse glass to ultra-violet irradiation is responsible for certain of these differences. However, Frey-Wyssling and Bäbler[1] were able to show that when greenhouse plants were irradiated with ultra-violet light the chlorogenic acid content of the leaves was increased, but that rutin was still absent, which implies that the apparent absence of rutin is not due to limited ultra-violet irradiation.

We have recently experimented in this Department with the flue-cured tobacco variety Hicks in order to see if satisfactory leaf can in fact be grown under glass. The plants were grown both in clay pots and polyethylene buckets containing washed quartz sand using the nutrient solution developed by McEvoy[4] supplied by means of a drip-feed system. The plants were handled in a similar manner to tobacco grown in the field; they were topped at sixteen leaves and suckers were removed as they appeared. The leaves were harvested as they became mature and cured in a small cabinet. After curing, the leaves had the appearance of tobacco grown in the field, and comparable plant yields were obtained.

Aqueous extracts of the green and cured leaves were examined for polyphenols by means of one- and two-dimensional paper chromatography[5], and in agreement with other workers it was found that the total amount of polyphenolic compounds was less than in field-grown tobacco. However, rutin (quercetin-3-rhamnoglucoside) was present in the extracts. No other flavonols or flavonol glycosides could be detected on the chromatograms. A useful spray reagent for the detection of flavonols consists of a freshly prepared mixture of equal volumes of boric acid (1 per cent in acetone) and citric acid (10 per cent in acetone). With this reagent the rutin spot turns yellow and shows a greenish-yellow fluorescence under ultra-violet light.

The rutin contents of several samples of cured greenhouse-grown tobacco were determined using a modification (Weaving, A. S., unpublished method) of the methods proposed by Wilson[6] and Guseva and Nestyuk[7]. It may be mentioned here that the method used by Turner[8] was not suitable owing to the interference by chlorogenic acid. The results obtained are given in Table 1 and are expressed on a moisture-free basis.

Table 1. RUTIN CONTENTS OF GREENHOUSE-GROWN TOBACCO

	Clay pot (per cent)	Polyethylene bucket (per cent)
Third harvest	0·24	0·23
Fourth harvest	0·24	0·24
Fifth harvest	0·29	0·28
Sixth harvest	0·37	0·33
Seventh harvest	0·39	0·43

These rutin contents are much lower than those of field-grown flue-cured tobacco, for which we have found values ranging from 1·0 to 1·7 per cent (Weaving, A. S., unpublished results).

It has been shown by Penn and Weybrew that cultural and curing practices can greatly influence the polyphenol content of tobacco grown in the field, and this aspect is now under investigation with greenhouse plants.

Thanks are due to the Directors of the Imperial Tobacco Company (of Great Britain and Ireland), Ltd., for permission to publish this communication.

HISTORY OF SCIENCE

Inertial Navigation

THE recent voyage of the submarine *Nautilus* below the polar ice has caused interest to be focused on the subject of 'inertial navigation'. This recalls to mind a communication which was published in *Nature* (7, 483; 1873). A correspondent, Joseph John Murphy of Co. Antrim, discounted the idea that "the instinct of direction in animals is of the same kind as the faculty by which men find their way" and suggested instead a mechanical analogy basically identical with 'inertial navigation', namely:

"If a ball is freely suspended from the roof of a railway carriage it will receive a shock sufficient to move it, when the carriage is set in motion: and the magnitude and direction of the shock . . . will depend on the magnitude and direction of the force with which the carriage begins to move . . ." ". . . every change in . . . the motion of the carriage . . . will give a shock of corresponding magnitude and direction to the ball. Now, it is conceivably quite possible, *though such delicacy of mechanism is not to be hoped for* [my italics, D. C.], that a machine should be constructed . . . for registering the magnitude and direction of all these shocks, with the time at which each occurred . . . from these data the position of the carriage . . . might be calculated at any moment."

Murphy went on to detail the possible mechanism by reference to the recording anemometers of his day, and even suggested dial indication of instantaneous distance and direction from the starting point.

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. H. T. Prior, Mr. D. J. R. Chapman and Mr. A. A. M. Whitehead: "The Application of Transistors to Line Communication Equipment".

Society of Instrument Technology, Control Section (at Manson House, Portland Place, London, W.1), at 6 p.m.—Mr. J. C. Kubale: "Control Systems as Applied to Railways Signalling".

Society of Chemical Industry, London Section (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. C. M. Berners-Lee: "Some Uses of Electronic Computers in the Chemical Industry".

Tuesday, January 6

Royal Aeronautical Society (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 3 p.m.—Dr. L. R. Shepherd: Lecture on Astronautics.

Institution of Chemical Engineers—(at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. R. Ll. Rees and Mr. F. J. R. Taylor: "Feed Water and Boiler Water Standards in the Central Electricity Generating Board"; Mr. J. Arthurs, Mr. J. A. Robins and Mr. T. W. Whitefoot: "The Treatment of Water for an Industrial High Pressure Boiler Plant".

Institution of Electrical Engineers, Measurement and Utilization Sections (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. H. Davis: "Silicone Electrical Insulation".

Institution of Mechanical Engineers, Internal Combustion Engine Group (at 1 Birdcage Walk, Westminster, London, S.W.1) at 6 p.m.—Discussion on "The Influence of Infinitely Variable Torque Conversion on Engine Design".

Society of Chemical Industry, Plastics and Polymer Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. W. Hechelhammer: "Polycarbonates—their Properties, Processing and Applications".

Society of Dyers and Colourists, London Section (joint meeting with the London Section of the Textile Institute, at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Prof. J. B. Speakman: "To Blend or not to Blend—That is the Question".

Wednesday, January 7

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. Dr. J. M. van der Vlerk (Leyden): "Problems and Principles of Tertiary and Quaternary Stratigraphy" (Fourteenth William Smith Lecture).

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5 p.m.—Miss V. R. Cane: "Behaviour Sequences as Semi-Markov Chains".

Institute of Petroleum (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. G. H. Clark and Mr. D. A. Davidson: "Petroleum-Based Launching Lubricants".

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 7.45 p.m.—Dr. R. C. Sutcliffe, F.R.S.: "The Nature of Weather Forecasting" (Second Evening Discourse).

Thursday, January 8

Institution of Naval Architects (in the Weir Lecture Hall, 10 Upper Belgrave Street, London, S.W.1), at 4.45 p.m.—Dr. J. C. Hudson, Mr. J. F. Stanners and Mr. A. G. B. Miller: "The Surface Preparation of Ship Plate (Outer Bottom Plating) for Painting".

Institute of Refrigeration (at the Institute of Marine Engineers, The Memorial Building, 76 Mark Lane, London, E.C.3), at 5.30 p.m.—Dr. G. G. Haselden: "An Economic Evaluation of Large Ammonia Absorption Refrigerating Machines".

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. L. G. Brazier: First Hunter Memorial Lecture.

Royal Aeronautical Society (at the Institution of Mechanical Engineers, Birdcage Walk, London, S.W.1), at 6 p.m.—Mr. R. Hafner: "The Tandem Rotor Helicopter".

Friday, January 9

Public Schools Appointments Bureau Conference (organized by the Plastics Institute, at the Borough Polytechnic, London, S.E.1), at 10.15 a.m.

Association of Applied Biologists (in the Meeting Room of the Royal Entomological Society, 41 Queen's Gate, London, S.W.7), at 10.50 a.m.—Symposium on "Insects and Public Health".

Institution of Electrical Engineers, Medical Electronics Discussion Group (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "The Physiologists' Requirements for D.C. Amplifiers" opened by Dr. M. H. Evans and Dr. G. B. B. Chaplin.

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. R. R. Arnold and Dr. P. W. Whitton: "Stress and Deformation Studies for Sandwich Rolling Hard Metals".

Society of Dyers and Colourists, London Section (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Dr. J. L. Ashworth, Mr. H. B. Mann and Dr. T. H. Morton: "Optical Brightening Agents in Action".

Saturday, January 10

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. W. Watson: "The Mizutori Ceremony of the Todaiji Temple in Nara: a Purification Ceremony After the New Year".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Chief Horticulturist (highly qualified, with an appropriate university degree, wide horticultural experience and preferably experience of tropical horticulture) in the Department of Research and Specialist Services, Ministry of Agriculture, Federation of Rhodesia and Nyasaland, to be responsible for advising on horticultural policy as well as formulating a suitable programme for horticultural research—The Secretary (R), Rhodesia House, 429 Strand, London, W.C.2 (January 17).

Assistant Lecturer, Grade A (male), at H.M. Dockyard Technical College, Singapore, to teach Mathematics and/or Science—The Director (Y), Education Department, Admiralty, London, S.W.1 (January 20).

Research Assistant (with a first- or good second-class degree in botany or zoology and training or research experience in cytology), to work on cytological effects of ionizing radiation in plants—Dr. G. R. Lane, Department of Botany, The University, Southampton (January 24).

Lecturer in Mathematics (Pure Mathematics) at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 27).

Lecturer in Chemistry, a Lecturer in Physical Chemistry, and Lecturers (2) in Geography at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 30).

Lecturers (2) in Zoology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 30).

Research Assistant (university graduate with research experience and with a knowledge of poultry husbandry) in Poultry Husbandry for duties which will involve the planning and execution of experiments concerned with husbandry problems, together with the interpretation of the results and the preparation of reports arising from the work—The Principal, Harper Adams Agricultural College, Newport, Shropshire (January 30).

Lecturer (honours science graduate, with experience in virology and in research methods) in Bacteriology—The Secretary, The University, Edinburgh (January 31).

Lecturer or Assistant in Statistics in St. Salvator's College, St. Andrews—Joint Clerk to the University Court, College Gate, St. Andrews (January 31).

Lecturer/Senior Lecturer in Agriculture (Biometrical Methods) and a Lecturer in Agronomy at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 31).

Lecturer (with a degree in electrical engineering and preferably experience in one or more of the fields of light current engineering) in Electrical Engineering at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 31).

Senior Technician (preferably with good qualifications in histology) in the Department of Zoology, University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, January 31).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Engineering, Pharmacology, or Physics—The Secretary, The University, Aberdeen (February 13).

Imperial Chemical Industries Research Fellows in Physics, Chemistry, Biochemistry, Engineering, Metallurgy and Pharmacology or any related subjects—The Registrar, The University, Liverpool (February 14).

Lecturer (with experience in one of the following fields of research: (*a*) adsorption and heterogeneous catalysis; (*b*) use of radioisotopes; (*c*) gas chromatography) in Physical Chemistry—The Secretary, The Queen's University, Belfast (February 14).

Lecturer in Mechanical Engineering—The Secretary, The Queen's University, Belfast (February 20).

Professor of Anatomy at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 28).

Research Fellow (Ph.D. standard) in the Department of Botany, to undertake research in the field of mycology and/or plant pathology—The Registrar, The University, Birmingham 15 (March 1).

Lecturer or Assistant Lecturer in Electronics—The Secretary and Registrar, The University, Southampton (March 14).

Lecturers or Assistant Lecturers (with experience in at least one of the following fields: generation, transmission and/or distribution of electrical power, measurements, electrical machinery) in Electrical Engineering—The Secretary, The Queen's University, Belfast (March 20).

Lecturer in Botany, a Lecturer in Zoology and a Lecturer in Biochemistry—The President, University College, P.O. Box 399, Addis Ababa, Ethiopia.

Physics Technician (preferably with a knowledge of electronics or vacuum technique), for work on a high voltage accelerator—The Administrative Officer, R.B.U. Medical Research Council, A.E.R.E., Harwell, Berks.

Scientific Assistant (Technician) (preferably with some experience of light engineering), to work on a project to develop special equipment for use in biological research and industry—Prof. O. L. Zangwill, Psychological Laboratory, The University, Downing Place, Cambridge.

TECHNICIAN (preferably with previous experience) FOR THE CHEMISTRY LABORATORIES—The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

The British Railway Locomotive 1803–1853: a Brief Pictorial History of the First Fifty Years of the British Steam Railway Locomotive. Compiled by G. F. Westcott. Pp. 14+32 plates. (London: H.M. Stationery Office, 1958. Published for the Science Museum.) 3*s*. 6*d*. net. [2410

SCIENTIFIC MAN-POWER AND DEVELOPMENT IN BRITAIN

THE eleventh annual report of the Advisory Council on Scientific Policy*, for the period July 1, 1957–June 30, 1958, is concerned with some aspects of three main topics: the organization and administration of scientific research; scientific man-power; and various measures which affect the efficiency with which scientific man-power is used. With the magnitude of the research effort of Great Britain, to which a large part of the previous report was devoted, the present report is scarcely concerned, other than to supply in an appendix revised figures for Government expenditure on civil research. These put the total for 1958–59 at £28·5 million, compared with £26·6 million in 1956–57. For the Research Councils the figures are: Scientific and Industrial Research, £11·4 million and £10·5 million; Agricultural Research, £5·08 million and £4·6 million; Medical Research, £3·1 million and £2·8 million; Nature Conservancy, £350,000 and £305,000. The total scientific staff employed was 6,449 in 1958–59, compared with 6,139 in 1957–58. As regards the distribution of this effort in 1958–59, £8,289,000 is for agriculture, forestry, fisheries and food; £13,386,000 for industry and communications; £3,860,000 for medical research and health; £1,735,000 for overseas research; and £1,064,000 for the Government Chemist, meteorology, oceanography and observatories.

On the organization of research effort, the report this year deals solely with the financing of scientific research in British universities, and that topic, with the exception of two aspects which are related to the effective utilization of scientific man-power and are discussed below, has already been considered in these columns (see *Nature*, December 27, p. 1757). On scientific man-power the Advisory Council reports that a more comprehensive review of the membership of professional institutions has been possible, and on this basis it is estimated that some 13,000 professional scientists and engineers qualified for the first time in 1957. This estimate takes account of the number of engineers with multiple qualifications without a university degree among the 7,900 admitted to thirteen professional engineering institutions; about 200 of nearly 900 new members admitted to the Royal Institute of Chemistry and the Institute of Physics had no university degree.

Figures from the University Grants Committee indicate a 13 per cent increase in graduates in engineering in 1956–57, but only about 3 per cent in pure science; and if, as expected in framing the building plans of the universities, some two-thirds of the additional students read for degrees in pure science and technology, the student population in these departments will increase from 35,000 (October 1957) to about 55,000 by 1966, a figure which should give about 12,000 graduate scientists and engineers a year, compared with 7,800 in 1956–57. By that date, too, it is expected that the technical colleges will be supplying about 9,500 scientists and technologists of professional status, and this figure might rise to 10,500 a year by 1970 if the expansion continues in the late 1960's. This total figure of 22,500 thus leaves a reasonable margin over the target of 20,000 set in the report on "Scientific and Engineering Man-power in Great Britain" published in 1956; and the Advisory Council appears to be satisfied, from the rising number of those staying on at school until the age of seventeen and from current estimates of the probable intake into universities, technical colleges and teacher training colleges, that there should be no lack of young people of ability to fill the larger number of places in the universities and technical colleges.

This position, however, emphasizes the critical importance of an adequate supply of science and mathematics teachers for the schools, and while the Advisory Council recognizes frankly enough that the effectiveness of the expansion plans ultimately depends on this, its current report is no more reassuring on this point than the previous one. The main pressure in the next few years will fall on the maintained schools, which are already short of graduate teachers of science and mathematics and have difficulty in recruiting staff with satisfactory qualifications. The position seems likely to grow worse, even though schools and institutions of further education have increased their staffs by about 500 graduate teachers of science and mathematics a year during the past four years. In 1956–57 the net increase rose to about 845, with a further increase of 120 in graduate engineers teaching in technical colleges; but this total in a particularly favourable year is still 400 short of the average annual increase required to raise the number of these teachers in schools and technical colleges to 29,000 in 1959—the number estimated as needed at the time of the earlier survey of scientific and engineering man-power in Great Britain. Since then the Committee on Scientific Man-power has suggested that a further 4,000 teachers would be needed to maintain staffing ratios in view of the increase in pupils in secondary schools, while the Willis Jackson Committee has estimated that technical colleges in England and Wales need to increase their graduate teachers of science and technology by 250 and 265 a year, respectively, and also recommended an increase in provision for full-time training in technical teacher training colleges from 300 to 500.

This shortage of science and mathematics teachers is only one aspect of a general shortage of teachers, and the Advisory Council welcomes the recent statement by the Minister of Education that within the programme to provide 12,000 new places in teacher training colleges in England and Wales by the autumn of 1962, special measures will be taken to train extra teachers of science and mathematics. No proposals, however, for specifically closing the gap have been forthcoming, nor are any advanced by the

* Annual Report of the Advisory Council on Scientific Policy, 1957–58. Cmnd. 597. Pp. 22. (London: H.M. Stationery Office, 1958.) 1*s*. 3*d*. net.

Advisory Council, and the shortage seems likely to continue. It is ignored in the latest White Papers dealing with secondary education. Rightly, the Council points out that it is the teachers now at work who bear the brunt of the pressure on the secondary schools. The increase in the output of scientists and engineers from the universities should ultimately increase the number of such graduates who take up teaching, and the introduction of more degree courses suitable for those intending to teach could also help; but neither measure meets the immediate emergency.

In these circumstances, the Advisory Council directs attention to the importance of measures which can ease the task of the science and mathematics teachers. The provision of more accommodation and the rapid modernization of laboratory and equipment are one way; the provision of laboratory assistance is another. There is indeed a continuing need for schools and colleges to show ingenuity in making the most of existing staff and facilities, but the task should not be left to them alone. At this juncture a generous policy in such matters would pay the nation most handsome dividends, and might well prove decisive in narrowing the critical gap. It should be urged on the Government and on educational authorities with all the emphasis and authority at the command of the Advisory Council and others who understand the importance of a sufficient supply of scientific and technical man-power.

The major importance of the Advisory Council's present report lies indeed in its comments on several of these factors which determine the effective use of existing supplies of scientific and technical man-power. In its previous report, it pointed out that the effectiveness of university research would be much enhanced by the comparatively small expenditure necessary to increase substantially the number of supporting staff in university laboratories. In the present report it returns to the problem at greater length.

In general, the responsibility for providing technicians rests, and must continue to rest, with the universities. The Research Councils may indeed finance the employment of specialist technicians if a university department, in applying for a piece of expensive and complicated equipment, can show that a specially qualified technician is also needed and cannot be recruited without financial assistance. University departments, however, have the utmost difficulty in obtaining technicians, and particularly in recruiting high-grade men with specialist qualifications. The Committee of Vice-Chancellors and Principals has now arranged an investigation into the work, qualifications and conditions of employment of technicians in university departments as compared with those of technicians outside the university field. Reiterating the conclusion of its previous report as to the large return to be reaped from comparatively small expenditure in this way, the Advisory Council stresses the futility of encouraging scientists to enter university research and then to deny them the kind of technical assistance which they would enjoy in Government or industrial research establishments. The private foundations have frequently given some assistance here, but the problem is primarily one for the universities themselves, and the Advisory Council is not alone in hoping that university authorities will, as a matter of urgency, consider how they can increase the supply of technicians available to their scientific and technological departments.

Related to this is the question of equipment. All the Research Councils make grants to meet the cost of special equipment required for the research projects which they are supporting; but present practice in the matter of more general research equipment is not uniform. The Advisory Council recognizes that it is more in accordance with university autonomy for the universities to finance the purchase of equipment themselves; but it also recognizes the need for special arrangements, including additional sources of finance, for certain kinds of expensive research equipment needed to-day in science and technology. Indeed, apart from the question of availability of finance, university departments may well be reluctant to embark on the installation of such equipment, because of the danger of distortion of effort and the difficulty of disengagement with change of staff.

Such reasons, and the further difficulty of ensuring that economic use is made of such equipment, have led to suggestions that it is best installed at independent research institutions; but that course involves removing important fields of research from university departments. The National Institute for Research in Nuclear Science is one attempt to meet this difficulty. As the Advisory Council on Scientific Policy points out, this provides, for common use, equipment which is beyond the scope of individual universities and institutions to provide for themselves. It has also been decided that the University Grants Committee should be responsible for grants for the purchase of electronic computers; but no special arrangements for providing through the University Grants Committee the various types of apparatus costing £2,000–£10,000 which are necessary in many fields to-day and which many university departments cannot purchase from their annual allocations of general-purpose funds.

Nor is this all. Modern equipment for general research purposes, besides increasing the effectiveness of research and the rate at which it can be carried out, adds greatly to the efficiency with which both scientists and technicians can be used. Accordingly, out-of-date equipment in our universities, when used for research as distinct from teaching, represents a drain on valuable man-power which is completely uneconomic and unrealistic. Add to this the continuing trend of equipment to increase in complexity and cost, and the delay which is often involved before newly developed or improved equipment, too expensive to be charged to the annual budget, can be obtained for general research purposes, and it is obvious that the Advisory Council is directing attention to a problem which offers considerable possibilities of a saving in man-power.

The University Grants Committee and the Research Councils are agreed that the former is not best fitted to deal with such specialized requests, and that it would be preferable for them to be considered by the appropriate Research Council or by the Government grant boards of the Royal Society. During the past two years, the Department of Scientific and Industrial Research has invited applications for grants to finance the purchase of expensive equipment, not only for particular research projects receiving its support, but also to facilitate progress in wider fields of research within the Council's general sphere of interest. The other Councils are willing to make similar arrangements, provided they receive sufficient funds for the purpose; and the Advisory Council on Scientific Policy hopes that by next year they will be in a position to invite requests for specific types of equipment required for research but unrelated to particular research projects. Furthermore, it recommends that the procedure and the scale of expenditure should be reviewed by the University Grants Committee and the Research Councils before the universities are asked to frame the proposals for the next quinquennium.

This, however, is only the beginning. It is not sufficient to ascertain the potential demand for such equipment or even for adequate funds for the purpose to be placed at the disposal of the Research Councils. It is no less important that the procedure should be flexible and swift in action, so that there is no undue delay in meeting an established and approved need. Here the question of Treasury control requires some forethought, and it is to be hoped that, in framing the proposals for administering grants for this purpose, due weight will be given to the evidence submitted recently to the Select Committee on Estimates relating to Treasury control of expenditure and to the Department of Scientific and Industrial Research.

A number of miscellaneous activities considered by the Advisory Council also bear on this question of making the fullest possible use of existing scientific and technical man-power in Britain, in the universities and elsewhere. The United Kingdom is participating in several projects of the Governing Committee for Scientific and Technical Personnel established in June 1958 by the Council of the Organization for European Economic Co-operation. These projects include an annual review of action taken in member countries to increase the supply of scientific and technical man-power; vacation courses for science teachers; and fellowships to enable senior lecturers or research workers to make short visits to research or training institutions in other countries. They should yield a considerable direct return for the United Kingdom's contribution of £15,000.

Again, the United Kingdom representative on the Science Committee of the North Atlantic Treaty Organization, which the North Atlantic Council decided on December 1957 to establish, is the deputy-chairman of the Advisory Council on Scientific Policy, Sir Solly Zuckerman. Apart from its consideration of problems in the field of defence science, this Committee has already considered a proposal to establish a substantial number of N.A.T.O. fellowships to be held by postgraduate students, primarily for study abroad, and also proposals for financial support for advanced study institutes for special subjects. The Council believes that this Science Committee can carry out a valuable function by stimulating and encouraging the activities of existing organizations in this field and by carrying out certain projects which are not being undertaken by other bodies. The Council's Committee on Overseas Scientific Relations has also reviewed the present organization and activities of the scientific missions attached to certain United Kingdom embassies, and the report enters a strong plea in support of the scientific attaché.

A review of the work of missions and attachés in recent years has convinced the Council that the outlay in money and personnel has been fully justified. Men with the combination of personal and scientific qualities necessary to make a first-class scientific attaché are relatively rare; but they perform a function which visiting specialists of international reputation in a particular field cannot fill, because they cannot give the continuity essential for the attaché's work. Much of an attaché's work is unspectacular but none the less valuable. The Advisory Council considers that the territory covered by one attaché is sometimes too large, and it also urges that appointments should not be limited to countries having a high current level of technical development.

While the Advisory Council fully recognizes that the resources of Britain are limited, its lead is unequivocable, though it might have argued more clearly the economic advantages of extending the system to other countries. Although the Council is clearly convinced of the advantages of more co-operation between the Western nations in scientific and technological research, and has re-constituted its Committee on Overseas Scientific Relations, it is by example rather than specific recommendation that the lead is given. Thus it welcomes the Government announcement that negotiations are proceeding with the London County Council for the lease of a site on the South Bank site to house a new building to accommodate the Patent Office and a new National Reference Library of Science and Invention built up from the existing Patent Office Library. The Advisory Council welcomes this somewhat belated decision, but it seems content to accept the delay of possibly five years before building even commences. No mention is made of the cost to the nation of this further delay and its implications.

There will, of course, always be differences of opinion as to the relative importance of particular proposals; but the Advisory Council on Scientific Policy has certainly directed attention to a varied range of issues which bear on the development in Britain of scientific and technical man-power. A programme of action and exposition is set forth clearly enough, to be pursued by those who appreciate the bearing on the future of Britain of the effective utilization of existing scientific and technical resources, and the need for early expansion of the supply of scientists, technologists and supporting technicians.

ANTHROPOLOGICAL STUDIES

Method in Social Anthropology

Selected Essays. By A. R. Radcliffe-Brown. Edited by Prof. M. N. Srinivas. Pp. xxi+189. (Chicago: University of Chicago Press; London: Cambridge University Press, 1958.) 28*s*. net.

The Scope of Physical Anthropology and Its Place in Academic Studies

A Symposium held at the Ciba Foundation, 6th November 1957. Edited by D. F. Roberts and J. S. Weiner. Pp. vii+66. (New York: The Wenner-Gren Foundation for Anthropological Research. Published for The Society for the Study of Human Biology, 1958. Obtainable from the Institute of Biology, 41 Queen's Gate, London, S.W.7.) n.p.

THE first part of this work of the late Prof. A. R. Radcliffe-Brown includes a number of his previously published essays in chronological order. These are concerned principally with the scope of social anthropology and its relation to other disciplines, mainly psychology and history. In the latter regard Radcliffe-Brown was at considerable pains to show that the problems of anthropology are quite different from those of ethnology. Social anthropology must also employ comparative methods, but with the aim of exploring varieties of social life as a basis for the theoretical study of human phenomena rather than of discovering historical connexions between peoples. It seeks not to 'explain', but to understand a particular feature of a particular society by first seeing it as a particular instance of a general kind of social phenomena, and then by relating it to a certain general tendency in human societies. Radcliffe-Brown returned to the comparative method in the first five chapters of an introductory work which was uncompleted at his death. These chapters, which are included in the present book, provide a very clear, if somewhat abbreviated, exposition of his scientific approach and employment of such central concepts as 'social structure', 'social organization', 'social evolution', etc. "R.-B.'s" many admirers and followers will be glad to have these posthumous essays and selection of writings within a single volume, although its actual title is slightly misleading. His main contribution to methodology is to be found elsewhere—in his "Structure and Function in Primitive Society" and in his "Introduction to African Systems of Kinship and Marriage".

The second of the volumes under review comprises some ten papers, read at a symposium in 1957 at the Ciba Foundation, with the object of defining the scope of physical anthropology and introducing it to those in cognate sciences. Sir Wilfrid Le Gros Clark, who opened the session, feels that physical anthropology is a historical subject in so far as it studies the organic relation of the human species to lower animals, its evolutionary origin, its differentiation into races and sub-races, and the relation of physique to different conditions of life in the past. He considers, however, that future research will be mainly directed to the study of living populations, particularly in regard to problems of human genetics. An investigation of the latter kind is described by A. C. Stevenson, who summarizes the results of an examination of population genetics in Northern Ireland. Experimental work is also the subject of A. E. Mourant and of N. A. Barnicot, the former being concerned primarily with organization for research in serology and the latter mainly with laboratory techniques in the study of living populations. Kenneth P. Oakley describes physical anthropology in the British Museum, and J. M. Tanner discusses the place of human biology in medical education. J. S. Weiner's contribution is devoted to the same topic. He points out that there is a dearth of teaching in human genetics and considers that this ought to be remedied in the universities. Physical anthropology could be taught at an elementary level as an educational or 'liberal' discipline as well as at an advanced level as a specialized professional subject. Prof. J. Z. Young also makes a somewhat similar point, arguing that human biology can help medical students over the boundaries between physical science and the cultural sciences. L. S. Penrose contributes a short paper about human variability and adaptability, and Sir Solly Zuckerman sums up.

KENNETH LITTLE

TECHNOLOGY OF THE INDUSTRIAL REVOLUTION

A History of Technology

Edited by Charles Singer, E. J. Holmyard, A. R. Hall and Trevor I. Williams. Assisted by Y. Peel, J. R. Petty and M. Reeve. Vol. 4: The Industrial Revolution, *c*. 1750 to *c*. 1850. Pp. xxxiii+728+48 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1958.) 168*s*. net.

WHEREAS each of the first two volumes of this great history holds some thousands of years between its covers, and the third about two hundred and fifty, this fourth volume covers only a hundred—from 1750 to 1850, the period of the Industrial Revolution. But what a hundred years! Although the Renaissance and the invention of printing had brought a liberation of men's minds, their daily way of life remained little changed from the days of the Roman emperors. Their clothes were still woven on hand looms, they still struck fire from flint, still travelled by sail and horseback and still battered each other to death with axe and sword. The changes which began in the middle of the eighteenth century well merit the word 'revolution' and it was happy for England that her revolution took this form and belonged particularly to her.

The first chapters of the book are devoted to farming (by O. Beaumont, J. W. Y. Higgs and G. E. Fussell) and they are followed by an unexpected chapter on fish preservation (with a note on whaling), covering its entire history. After chapters on mining and the extraction of metals (the first extending up to 1875, for occasionally the articles rightly over-run the Industrial Revolution), the dominant subject of power is dealt with in three masterly essays. Prof. R. J. Forbes writes on the general development of motive power up to 1850, the late Dr. H. W. Dickinson deals specifically with the steam engine (a miracle of condensation, in both senses) and his successor at the Science Museum, A. Stowers, gives a concise history of waterwheels from 1500 up to 1850, referring much to the work of John Smeaton, "who could not touch anything without improving it" and whose name occurs *passim* throughout this volume.

Having established the basic elements of the Industrial Revolution—power and the metals—the development of the manufactures comes under discussion. It would have been impossible to describe all the by-ways of industrial chemistry in such a work as this, so Dr. E. J. Holmyard writes on the progress of chemical theory and practice, while A. and N. L. Clow give a survey of the chemical industry and the way in which it interacted with the Industrial Revolution. The Clows also describe the growth of the pottery industry and wisely illustrate (among the plates) the beautiful ware of which they write.

Gas for lighting and heating is so much a British industry that Sir Arthur Elton's emphasis on the pioneer work on wood-distillation of Philippe Lebon is timely. Nevertheless, it seems a little over-stressed when compared with the practical results with coal of William Murdoch (his name is better spelt thus: the 'k' was merely a sop to the pronunciation of Southerners). Textiles (by Julia Mann and W. English) naturally have long articles, which are purely technical and do not deal with the growth of the 'factory system' and the attendant changes in the people's life—this is not a social history.

Machine tools, the handmaidens of the Industrial Revolution, are split into two sections, and one of the few foreign contributors, Maurice Daumas, of the Conservatoire National des Arts et Métiers, leads off with the largely French work in the field of precision mechanics used in making clocks and instruments. He unwittingly reveals the answer to a famous vexed question among gas-engineers—why the general public insists on calling 'gas-holders' by the familiar term 'gasometers'. It is because Lavoisier did so in his laboratory some twenty years before coal-gas was manufactured. K. R. Gilbert adds a definitive chapter on the machine tools of the engineer (containing the morbidly ambiguous note, "Clement built planer, manufactured taps and dies").

Dr. S. B. Hamilton, on building and civil engineering construction (the longest single contribution), describes the development of structural theory during the period (the era of cast and wrought iron) and links it with the great achievement of the new race of 'civil engineers'. Prof. Forbes's second article, on roads, takes us up to 1900, and it is sad to think that a hundred years have elapsed since Telford and McAdam (whose name is so often mis-spelt in other books) put Great Britain ahead of the world in this craft and we have been losing our position as road-builders ever since.

The chapter on ship-building is extraordinary, for it is devoted almost entirely to sailing ships. The use of steam is dismissed in a paragraph; yet the technique of marine engine building was founded and developed during the period in question, and the work of John Penn and of the firm of Maudslay, Sons and Field, among others, seems worthy of inclusion. This and railway engineering (which is entirely overlooked in this volume) are startling omissions from a book dealing with the technology of the Industrial Revolution.

This was not the era of electricity, but it gains an important place in the chapter on telegraphy by G. R. M. Garratt, and to complete the survey, there are good articles on glass, canals, sanitary engineering, cartography (another unexpected choice) and dredging.

Finally, there is an interesting, but rather diffuse, chapter by Prof. A. R. J. P. Ubbelohde summing up the change of technology from a 'craft mystery' to an exact science. This covers the whole period of the preceding volumes also, and deals with, among other things, the foundation and contributions to technological progress of the Royal Society, the French Encyclopædists and the British Association for the Advancement of Science. A tribute to the École des Ponts et Chaussées would have been appropriate here for, more than any other body, it gave the lead to civil engineering, and, as Dr. Hamilton shows in his article, produced some of the greatest constructional engineers and theorists of the period.

Much of the delight which this volume gives is due (as with the others) to the beautiful line drawings of D. E. Woodall, which embellish nearly every page. It would be carping to point out errors—inevitable in a work of this magnitude—but one cannot overlook the misattribution (to Telford) of Burdon's iron bridge over the River Wear, on Plate 29. As with all books cast in this mould, at first one is stunned by its apparent comprehensiveness; but on a second reading one becomes conscious of omissions (mostly caused by the limitations of space) and one yearns for a more detailed treatment of the various subjects. If an enterprising publisher were to invite each of the many contributors to re-write his chapter and expand it to the length of a book (with the same fine typography and drawings of this series), there would be created thereby a library of the technological achievements of the Industrial Revolution which would remain the standard reference for very many years.

G. B. L. Wilson

OCCULT VIRUSES

Symposium on Latency and Masking in Viral and Rickettsial Infections

The Proceedings of a Conference held at the University of Wisconsin Medical School, September 4, 5 and 6, 1957. Edited by Duard L. Walker, Robert P. Hanson and Alfred S. Evans. Pp. xi+202. (Minneapolis, Minn.: Burgess Publishing Company, 1958.) 4.75 dollars.

At one time when a virus was harboured by an organism, be it plant or animal, without apparent signs of its presence, it was thought sufficient to speak of it as a 'latent' virus. With the advance of knowledge, however, it became clear that there was more than one form of latency, and various expressions came into use to describe the phenomenon, not all of which were used with the same meaning by different authors. These expressions included such terms as 'symptomless', 'sub-clinical', 'inapparent' or 'latent'. Furthermore, as it became clear that in some cases the lack of overt symptoms depended on changes in the virus itself and not on the host, the situation became still more confused. For example, a 'masked virus' has been defined by Shope as one which is not itself directly demonstrable but is known to be present by circumstantial evidence. For some virologists, however, 'masked' sometimes means 'not infective', for others 'not detectable'. For many plant virologists masking could either mean that the lack of symptoms was a permanent natural phenomenon or that it could be brought about temporarily by changes in the environment.

In 1957, a conference attended by many leading virologists was held at the University of Wisconsin Medical School, first to discuss the underlying mechanism of virus latency and secondly to try to reach some agreement on the nomenclature and meaning of particular terms. The results of this conference have now been published and the book is dedicated to the late Dr. Francisco Duran-Reynals for his staunch advocation of the role of latent viral infection in the etiology of cancer.

So far as the nomenclature of latency was concerned, agreement was finally reached on a number of definitions. The term 'inapparent infection' was suggested to cover the whole field of virus infections which give no overt sign of their presence. The expression 'latent virus' is no more, and its place is taken by 'latent infection', which is 'inapparent infection' in a chronic condition where a certain host – virus equilibrium has been established. The use of the word 'masked' is discontinued and 'occult virus' is substituted to describe the cases where virus particles cannot be detected and in which the actual state of the virus cannot as yet be ascertained. 'Occult' viruses do not appear to fulfil Lwoff's precept: "in order that an infection, whether apparent or not, should be recognized as viral, infectious particles have to be detected and identified as a virus".

For viruses which have been shown to have developmental stages, the terms 'provirus', 'vegetative virus' and 'infective virus' are suggested.

As regards latency at the virus – cell level, a 'moderate' virus is one growing in a cell while still permitting its continued survival, a 'cytocidal' one kills the cell, and 'sub-moderate' covers intermediate cases.

While these definitions may not be acceptable to all virologists, the conference has served a most useful purpose in paving the way to a more stable nomenclature of the subject. The discussions on the underlying causes of latency are stimulating and may help to throw some light on this fascinating partnership between virus and cell.

KENNETH M. SMITH

THE TECHNOLOGY OF TRANSISTORS

Transistor Technology

(Bell Telephone Laboratories Series.) By Members of the Technical Staff of Bell Telephone Laboratories. Vol. 1. Edited by H. E. Bridgers, J. H. Scaff, and J. N. Shive. Pp. xxxvii+661. 131*s.* 6*d.* Vol. 2. Edited by F. J. Biondi. Pp. xiii+701. 131*s.* 6*d.* (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1958.)

THE ten years of intensive research which have followed the discovery of transistor action have been very fruitful. The two key materials, germanium and silicon, are now widely prepared with a purity and crystalline perfection unsurpassed for any substance; their bulk and surface properties have been exhaustively examined and the results have enabled theoretical advances to be substantiated. The properties of transistors have been explained very fully in physical terms and suitably expressed for use by electrical engineers. Metallurgical, physical and electrolytic methods of preparing transistors—with their key dimension, base-width, controlled to a micron or so—have led to production-lines the combined output of which now exceeds a million transistors a week. The impact on electronic equipment is beginning to be felt. But while the scientific, technical and review publications have devoted increasing space to all sides of the subject, the more advanced text-books have concentrated much more on analysing and applying the electrical properties of transistors than they have on describing methods of preparing the semiconductors and the many practical junction structures.

The Bell Telephone Laboratories played a major part throughout these ten years, for they followed up their original discovery with the first junction transistor, the first measurements of drift mobility and lifetime of minority carriers, zone refining and zone levelling, grown and diffused structures, the solar battery and other advances. There was much to look forward to, therefore, when it was announced that three volumes in the Bell Telephone Laboratories series of text-books were to be entitled "Transistor Technology". But 'technology' has no precise meaning; the Concise Oxford English Dictionary gives "the science of the industrial arts", a definition which, it might be argued, includes only those parts of a subject which have been based on empiricism. A wider meaning is applied here, however, particularly to Vol. 2, much of which is devoted to the analysis or prediction of the behaviour of the conventional three-terminal, three-layer transistor, of tetrodes and unipolar transistors, and of two- and four-layer diodes.

Vol. 1 is primarily a history of the developments made before April 1952, until when the Laboratories had had almost a monopoly of the main advances; in that month they disclosed their processes and design procedures to prospective licensees. What was then prepared is now published, with a little, but scarcely enough, revision in the light of later developments. The many comparative newcomers to the subject should read it, at least once. It does not demand much concentration, but it does convey something of the early atmosphere, when the subject was spreading so rapidly into several different fields of science. Some parts retain much of their importance, for example the preparation of germanium and the measurement of its key properties, while others, for example the fabrication of point transistors, have lost theirs.

Vol. 2 deals with some of the progress since 1952; it is essentially the reprinting of many papers, mostly by authors from the Laboratories. The introductory remarks to the different headings, under which the papers are grouped, are generally too short to weld the collection together and are uncritical. The opening chapter, a fairly recent review of the technology of silicon, with 156 references, moves at such a high speed that few points receive detailed description; but it is followed by good accounts of floating-zone refinement and zone levelling. The lengthy chapters which come next, on the design of diodes and triodes, contain many analyses of behaviour and include well-known papers by Ebers and Moll, Kingston, Moll and Ross, Pritchard, and Webster. Descriptions of a field-effect transistor and the solar battery follow; and the book concludes with a group of papers on those surface effects which have assumed importance in their own right and on which may well depend the reliability of transistors and hence the practicability of some large equipments now under development, each incorporating 10,000–30,000 transistors.

Only an interim assessment can be made of this large venture pending consideration of Vol. 3. But two points can be made already. The disjointed structure of Vol. 2 comes as a disappointment; and the undue length of some sections of Vol. 1, and the availability of almost all of Vol. 2 in well-known periodicals, promotes a sense of redundancy. The gap in text-book coverage may not be closed, despite the resources mustered.

J. R. TILLMAN

Ptaki Ziem Polskich

Tom II. By Jan Sokolowski. Pp. 569 (66 plates). (Warszawa: Państwowe Wydawnictwo Naukowe, 1958.) Cena zl. 85.

IN this second volume of "The Birds of Poland", Sokolowski deals with the Striges, Accipitres, Columbae, Pterocletes, Galli, Gressores, Phoenicopteri, Grues, Otides, Ralli, Laro-Limicolae, Lamellirostres (Anseres), Steganopodes, Tubinares, Podicipedes, Colymbi and Alcae, that reside in, migrate through, or visit Poland. He follows the same classification as in Vol. 1, which was reviewed in *Nature*, 182, 972 (1958).

The wealth of interesting information and acute observation collected in this volume is of great value to the ornithologist and the nature lover, but, as in Vol. 1, the generalized and organized treatment of the data is sadly missing. At least one of the author's remarks cannot remain unchallenged. He states that birds which soar do so only by thermal lift and only between 10 a.m. and 4 p.m. (pp. 42 and 182), but ignores the three other known sources of lift which are also used by birds in soaring flight: (*a*) the orographic lift during windy days over hilly country, which occurs at all times of day and under all conditions of cloud cover; (*b*) the wave-lift that occurs even under a complete cover of lenticular alto-stratus which enables birds such as vultures and kites to hang in the sky on the crest of the wave, for hours at a time; (*c*) the dynamic lift at all hours of the day and under all conditions of cloud cover utilized by those experts in soaring, the gull and the albatross, which sweep over the water using the wind-gradient and the up-currents created by the air blowing over the waves.

As in the first volume, the text is well illustrated with black-and-white drawings, but the numerous half-tone plates are badly reproduced from well-chosen photographs. It is regrettable that no scale is given in the colour plates, which are well drawn but poorly produced. The glossaries are very useful but contain some errors in spelling.

B. NOWOSIELSKI-SLEPOWRON

The Succession of Life through Geological Time

By Kenneth P. Oakley and Helen M. Muir-Wood. Third and revised edition. Pp. vii+94 (12 plates). (London: British Museum (Natural History), 1956.) 4*s*.

Fossil Amphibians and Reptiles

By W. E. Swinton. Second edition. Pp. ix+118+17 plates. (London: British Museum (Natural History), 1958.) 5*s*.

Fossil Birds

By W. E. Swinton. Pp. vi+63+11 plates. (London: British Museum (Natural History), 1958.) 5*s*. net.

ORIGINALLY prepared as a guide to an exhibit in the Department of Palæontology of the British Museum (Natural History) in London "The Succession of Life through Geological Time" has now appeared as a third edition. Its merits may be judged by the fact that it has achieved the independent status of a junior text-book in schools and universities in many parts of the world. In the new edition the text has been brought up to date and all the plates of vertebrate restorations have been replaced by original designs. Another well-known guide, Dr. W. E. Swinton's "Fossil Amphibians and Reptiles", has also appeared in a new edition. This handbook aims at giving a conspectus of the subject which can be used by the visitor in the galleries and also perused at leisure afterwards. It includes sufficient detail to be of value to the advanced student as well as the general reader. Based on the rich series of fossils in the Department of Geology of the Museum, it refers, where necessary, to material in other museums, and also directs attention to gaps in the national collection. The appearance of this handbook has been followed by another prepared by Dr. Swinton, "Fossil Birds". Its plan is similar to that of "Fossil Amphibians and Reptiles". Unlike amphibians and reptiles, however, which bulk largely in the fossil record yet are of slight importance in the living fauna of Britain, birds form an outstanding feature of the living fauna all the world over, but are only an insignificant element in the later geological formations. Nevertheless, these remains, which are well represented in the Museum collection, include many of first-rate interest and importance, of which *Archæopteryx*, the first known bird, is *facile princeps*; the original specimen of this famous 'missing link' is one of the Museum's greatest treasures. All three volumes are distinguished by some original designs by Maurice Wilson; they contribute greatly to publications of which the Museum staff may well be proud.

Feedback Control Systems

By Prof. Otto J. M. Smith. (McGraw-Hill Series in Control Systems Engineering.) Pp. xviii+694. (London: McGraw-Hill Publishing Company, Ltd., 1958.) 101*s*. 6*d*.

A WIDE range of linear and non-linear control systems are considered here, and methods described for the analysis and design of these various systems. The book is arranged simply, having four parts. In Parts 1 and 2 the author deals with the analysis and synthesis of linear systems. Linear techniques include descriptions of the use of s-plane plots, root locus constructions, the G-plane (Nyquist) polar plot, Bode diagram, Routh's criterion, and impulse response calculation from the poles and zeros on the s-plane. Techniques are presented for analysis of linear systems with random input signals, and for their optimum design on the basis of minimum error power. The behaviour of systems containing a time-delay in the closed loop is considered, and the 'Posicast' control (a form of linear predictor control) of such systems is described.

Parts 3 and 4 present techniques for non-linear systems. Much of the analysis is concerned with relay systems, using phase plane and describing function methods. Unilateral and bilateral non-linearities are also considered, where saturation, hysteresis, and backlash are included among the examples taken. Synthesis of non-linear systems employing predictor control is dealt with in some detail, it being assumed here that the system is of the saturating type. The final chapter describes the fundamentals of carrier type control systems.

In general, the theory is adequately supported by worked examples, of which the chapters on non-linear systems are in fact almost entirely composed. Part 3, which purports to deal with the analysis of non-linear systems, would have benefited if a complete account of relevant techniques had been given, to include omissions such as non-linear systems with random inputs, and sampling systems. In common with many modern books on the subject, too much emphasis is placed on detailed analysis, and too little on the simple basic generalities. There is, however, very much to recommend the book to final-year and postgraduate students, especially in regard to relay systems and predictor control. M. J. SOMERVILLE

CARBON MONOXIDE CONTENT OF THE BLOOD AND OTHER OBSERVATIONS ON WEDDELL SEALS

By Dr. L. G. C. E. PUGH
Division of Human Physiology, National Institute for Medical Research, London

During a recent study of blood carbon monoxide levels in men living at Scott Base, Antarctica, it was found by chance that the blood of a Weddell seal contained as much carbon monoxide as the blood of men who are heavy smokers. As this finding appeared to be of some theoretical importance, further samples were collected and analysed for carbon monoxide.

Blood samples were obtained from seals which were being slaughtered to provide dog food. The animals were either shot or killed by a blow on the head with an ice-axe; blood was collected immediately from the neck vessel, or, in some cases, from the wound itself. The anticoagulant used was heparin. The bottles containing the blood were carried in the pocket to prevent freezing. The samples were analysed on the same day, using the special method of Scholander and Roughton[1] for small quantities of carbon monoxide. Determinations of carbon monoxide on human non-smokers were carried out by the same method on samples of venous blood. Acid-base and electrolyte determinations were made in Christchurch, New Zealand, on a specimen of plasma brought back to New Zealand in the frozen state. The seal from which the specimen was obtained was a large female which was killed with an ice-axe as it lay asleep on the ice near Scott Base. The animal did not breathe again after the blow on the head, but the heart went on beating for about 30 min. The point of the ice-axe penetrated the brain near the mid-line, causing profuse pulsatile hæmorrhage. Two 50-ml. nylon centrifuge tubes were filled with blood and closed with metal caps without trapping air. The samples were centrifuged within $\frac{1}{2}$ hr. and the plasma transferred to a specimen bottle under oil. The bottle was filled completely, and the screw cap replaced without trapping air bubbles. It was then placed out of doors to freeze. Plasma bilirubin was determined in London on a specimen from another animal. In neither of these samples was there any visible hæmolysis.

The results are shown in Tables 1–4.

It can be seen from Table 1 that the carbon monoxide content of blood samples taken from Weddell seals was on the average six times as high as the mean value for human non-smokers. The results are, in fact, comparable with the range of values usually found in persons who are heavy smokers, which is 0·5–1·5 per cent[2,3]. The oxygen capacity and hæmatocrit values were higher and the red-cell counts lower than normal values for man, implying larger red cells containing more hæmoglobin (Table 3). The large size of the red cells was confirmed by microscopic examination of blood films; although no measurements were made, the red cells of blood from Weddell seals were judged to be 9–10μ in diameter, a value of 7μ being assumed for the human red cells with which comparison was made. The oxygen capacity and hæmatocrit results were similar to values reported on related species of seal[5–7]. The red cell counts, on the other hand, were lower than the results of Harrison and Tomlinson[5] on *Phoca vitulina* pups (4·7–8·5 million per cu. mm.) and *Halichoerus grypus* (5·8 million per cu. mm.), which suggests that the red cells in the Weddell seal are larger than in related species.

The plasma electrolyte values of seal No. 6 of Table 1 are shown in Table 4. The results are similar to the normal values for man, except for the high potassium value, which is unexplained. A specimen of urine from the same seal was analysed with the following results: specific gravity, 1·035; urea, 2·5 gm. per cent; sodium, 138 m.equiv./l.; potassium, 47 m.equiv./l. The bilirubin concentration of a specimen of plasma from seal No. 4 was 1·5 mgm. per cent, which may be compared with the normal human range of 0·3–0·7 mgm. per cent by the same method.

It has been known for some years that small quantities of carbon monoxide are present in human blood, even in persons who neither smoke nor have been exposed to any other source of carbon monoxide[8,9]. A series of papers by Sjöstrand[9,10] has provided convincing evidence that carbon monoxide is formed in the body during the breakdown of hæmoglobin to bile pigments, and is excreted quantitatively via the lungs, the hypothesis being that one molecule of carbon monoxide is liberated when each of the porphyrin rings in the hæmoglobin molecule splits. Under certain conditions carbon

monoxide may also be oxidized in the muscles and in the blood[9,11-14]. The presence of carbon monoxide has been demonstrated in the blood of other animals as well as man; in cattle, sheep and pigs the values found by Sjöstrand[9] were intermediate between the present figures for human non-smokers and Weddell seals, namely, 0·3–0·59 vol. per cent.

In the light of these findings, the level of carbon monoxide in the blood of an animal at rest, and in the absence of absorption from without, can be regarded as representing an equilibrium between formation of carbon monoxide by the breakdown of hæmoglobin and its elimination via the lungs. The rate of formation will depend on the total quantity of hæmoglobin in the body and the survival-time of the red cells. Elimination will be governed by the carbon monoxide tension of the blood, the rate of ventilation of the lung alveoli and the diffusing capacity of the lungs for carbon monoxide.

Which of these factors might account for the high content of carbon monoxide in the blood in Weddell seals?

Total hæmoglobin. The hæmoglobin concentration in the seals examined was 40–50 per cent higher than the average value for human adults living at sea-level. No information is available on the blood volume of Weddell seals, but determinations on the related species *Phoca vitulina*[5] and *Cystophora cristata*[7] suggest that it might be at least 50 per cent higher in proportion to body-weight than in man. In this case the total amount of hæmoglobin in the body would be about twice as great as in man, and for a given red-cell survival-time, the rate of destruction of blood, and therefore formation of carbon monoxide, would also be twice as high. Consistent with this is the high bilirubin content of plasma from one of the Weddell seals. A high plasma bilirubin value has also been reported in *Phoca vitulina*[6].

Hæmolysis. We were impressed at Scott Base with the difficulty of preventing hæmolysis in samples of seal blood. Much greater care had to be taken with them than with human blood samples. Similar observations have been made by Harrison (personal communication). This observation suggests that the fragility of the red cells of seal blood may be greater than in man, and if this is so it would contribute to a high rate of destruction of blood.

Myoglobin. Another possible, though less important, source of carbon monoxide is the myoglobin muscle, which is present in high concentration in the muscles of seals and is responsible for their very dark colour. It has been estimated that the total amount of myoglobin in seals is equivalent to about 25 per cent of the total hæmoglobin[7]. Nothing is, however, known of the turnover of myoglobin in the body.

Ventilation. The following scattered pieces of information suggest that high carbon monoxide values in Weddell seals may be associated with their habit of sleeping for prolonged periods of time on the ice surface, during which their ventilation may be very low. Seals lying on the ice within sight of our camp could be seen in the same position for days at a time. The animals from which blood samples were taken had empty stomachs (apart from parasitic worms) and in some cases the intestines also were completely empty, suggesting that they had been out of the water for a considerable time. No attempt was made to study ventilation in Weddell seals. It was recorded, however, that during sleep their respirations were so infrequent that patience was needed to see them breathe at all. When startled they would rear up and turn their heads to look at the intruder, and one could see them open their slit nostrils to breathe 12–13 times a minute. According to the surface-volume law[15] the resting ventilation of Weddell seals weighing 250 kgm. would be expected to be about 25 per cent lower than in man, and if their respiratory quotient is of the order of 0·73 when in the fasting state[16], the ventilation during sleep may well be as little as 60 per cent of the corresponding resting value in man (respiratory quotient, 0·83), in which case pulmonary elimination of carbon monoxide would be reduced during sleep and the blood-level would gradually rise.

Later in the season three further blood samples were obtained from seals which had recently appeared on the ice in another place near open water. The stomachs of these animals were full of small fish (*Notothenia*). The carbon monoxide values were

Total plasma carbon dioxide	27·5 m*M*/l.	

The undetermined anions are calculated by difference between the total fixed anions and plasma chlorides.

0·30, 0·45 and 0·67 per cent with hæmatocrits of 60·5, 63·5 and 55·0, respectively. Unfortunately, small clots were present in these samples, and the results were rejected. Later in England, an analysis was performed on a blood sample from a seal (*Phoca vitulina*) shot in the Wash by Prof. R. J. Harrison, and a carbon monoxide value of 0·19 vol. per cent was obtained. These seals, apart from their small size (that is, 25–50 kgm.), differ in their habits from Weddell seals in that they spend nearly all their time in the sea, coming out at low water on sandbanks exposed by the tide ; hence it may be assumed that their ventilation while they are at sea is high enough to keep down the level of carbon monoxide in the blood.

Low resting ventilation due to the factors mentioned above is consistent with a normal blood pCO$_2$ and pH such as was observed in the single plasma sample examined. It would not, however, be surprising to find hypoventilation with elevation of blood pCO$_2$, and high oxygen extraction-rates in seals at rest in the natural state, since there is experimental evidence that they are insensitive to carbon dioxide and also tolerate extremely low oxygen tensions[5,6]. This has not, however, been observed under experimental conditions[16].

Exogenous carbon monoxide. It remains to inquire whether there are any possible exogenous sources of carbon monoxide to which the Weddell seals near Scott Base might have been exposed. There is a remote possibility that carbon monoxide might be given off from the ooze on the sea bed and might be present in the ice pockets under the ice which seals are alleged to make use of; but there are no data to support this. Another possible source of carbon monoxide would be the neighbouring active volcanic Mount Erebus, but this is ruled out by the low values of carbon monoxide in persons at Scott Base who were non-smokers.

It seems reasonable to suggest, therefore, that the carbon monoxide in the blood of Weddell seals is the result of a balance between production of carbon monoxide in the body and elimination by the lungs, and that the high values reflect special features of the physiology of Weddell seals connected with their life under the ice and upon its surface.

Thanks are due to Mr. J. T. Murray, of Christchurch Hospital, Christchurch, New Zealand, who performed the acid-base and electrolyte determinations, and to Prof. R. J. Harrison for a blood sample from a harbour seal (*Phoca*).

THE LYMPHOCYTE PROBLEM

By PROF. J. M. YOFFEY
Department of Anatomy, University of Bristol

THE lymphocyte has for many years confronted us with a two-fold problem. The first concerns the rate at which lymphocytes are formed, the second the fate and functions of the lymphocyte once it has been formed. The great interest of the problem resides in the fact that the lymphocyte is present from the very beginning of vertebrate evolution, and may be presumed to play an essential part in the life of the organism.

What is a Lymphocyte ?

The question : 'What is a lymphocyte ?' is not as simple to answer as many have thought. The lymphocyte is a mononuclear cell, with a nucleus which may be round or indented. Lymphocytes are roughly classified in accordance with size as large, medium or small. The larger cells possess a fair amount of cytoplasm, sometimes basophilic. The most numerous—and also the most controversial—lymphocytes are the small variety, in man about 8μ in diameter. These cells possess very little cytoplasm, often only a small tuft at one pole of the cell. The high ratio of nucleus to cytoplasm is very characteristic of the small lymphocyte, and has led many to conclude that this cell functions essentially through its nucleus, for example, as a carrier of deoxyribonucleic acid. The small lymphocyte is also capable of movement of a very distinctive type. The movement may start quite suddenly and end equally abruptly. The nucleus goes first, often forming a round head, while the scanty cytoplasm forms a short stumpy tail. When not moving, the cell becomes rounded once again. The small thymocyte moves in the same distinctive manner.

Where are Lymphocytes formed ?

Lymphocytes in mammals are formed in the lymphoid tissues, which are aggregates of several different kinds of cells among which the lymphocytes predominate. Lymphoid tissue is present in all vertebrates. In fishes, amphibians and reptiles it is closely associated with the myeloid tissues which give rise to the red cells and granular leucocytes (granulocytes), and together with these it constitutes the so-called lymphomyeloid organs. In birds and mammals, most markedly in the latter, the lymphomyeloid tissues dissociate, and the lymphoid tissues seem to be quite separate from the myeloid. But the separation is not as complete as would at first sight appear. Even in mammals, there are always large numbers of scattered lymphocytes to be found in the myeloid tissues, while on the other hand, myeloid cells may not infrequently develop in the lymphoid tissues.

The Lymphoid Complex

The lymphoid tissues in mammals form a complex consisting of: (*a*) lymph glands; (*b*) spleen; (*c*) subepithelial lymphoid tissues such as tonsils, adenoids, Peyer's patches and appendix; (*d*) thymus. The scattered nature of the lymphoid tissues makes it difficult to estimate their total amount, but they probably constitute 0·5–1·0 per cent of the weight of the body. The position of the thymus in the lymphoid complex has been repeatedly questioned, and it has been suggested that though the small thymocytes look very like the small lymphocytes they are in fact a different type of cell. On the whole, the balance of evidence appears to favour the inclusion of the thymus in the lymphoid complex, and there is even some evidence to suggest that it may play a dominant part. Differences between the various members of the lymphoid complex may be the result of circulatory and metabolic peculiarities. Thus, to give but one example, lymph glands are traversed by a stream of lymph, reaching them by afferent and leaving by efferent vessels. In the case of the mesenteric lymph glands, the afferent lymph vessels bring products of digestion, whereas in the case of the limbs, the lymph stream contains waste products of tissue metabolism.

Lymphocyte Formation

Lymphoid tissues were among the first animal tissues in which mitoses were described—by Flemming in 1885. He noted the presence in lymph glands of the characteristic lymphoid nodule, a light central area of larger cells surrounded by a peripheral zone of smaller cells. It was in the lighter area that Flemming observed numerous mitoses, and he considered them to be germinal centres, in which there was active cell proliferation. One also finds that cell multiplication can occur in diffuse lymphoid tissue, devoid of nodules. Lymphocyte formation is often at its most active in the thymus, where germinal centres are not normally found. The centres undergo cyclic changes; they are also readily damaged by a variety of toxic substances. There may be few or no mitoses in either the resting or the damaged germinal centres. In the active centre, the growing cells show rapid uptake of phosphorus-32 or tritiated thymidine, both of which become incorporated into newly formed deoxyribonucleic acid, and these substances can readily be identified in autoradiographs.

Estimation of Lymphocyte Production

The histological evidence indicates that lymphoid tissues are regions of active lymphocyte formation. Many, if not all, of the lymphocytes thus formed enter the blood. They may do so indirectly, first obtaining access to the lymph stream and then being conveyed by it to the blood; or directly, through the walls of blood capillaries in the lymphoid tissues. 'Direct entry' lymphocytes cannot be measured. 'Indirect entry' lymphocytes can be counted since the lymph of the entire body reaches the blood mainly through the thoracic duct, and to a lesser extent through the right lymph duct.

It is a relatively simple procedure in most animals to collect the lymph from the thoracic duct, and count the lymphocytes which would otherwise have gone into the blood. One can also estimate the total number of lymphocytes in the blood stream. These in health remain fairly constant, and there is no evidence that they are destroyed while in the blood. The number of lymphocytes entering the blood each day via the thoracic duct is sufficient in the dog to replace those already present in the blood about 2·5 times. This is called the 'daily replacement factor'. The only way then in which the blood lymphocytes can maintain a constant level is for some to leave the blood at the same time as other newly formed cells are entering it. This at once raises the problem: Where do the lymphocytes leave the blood?

Is there a Lymphocyte Circulation?

The continued entry into the bloodstream of large numbers of newly formed lymphocytes has been questioned by several observers, who have suggested that what is really happening is the continuous circulation of lymphocytes between blood and lymph. There is no doubt that a small proportion of lymphocytes do circulate in this way, and it may be that in some species the number of recirculating cells is greater than in others. But the evidence on the whole indicates considerable new formation of cells in the lymphoid tissues. This has been estimated by mitotic counts, and by the rapid uptake of labelled deoxyribonucleic acid precursors.

Fate of the Lymphocyte

There are not many regions of the body which might be in need of a constant influx of cells. The most probable tissue appears to be the bone marrow, and quantitative studies indicate that it has a surprisingly large population of lymphocytes, which do not appear to be formed in the marrow. But why should the marrow be in need of continual cellular replenishment? Many have held that the lymphocyte is a primitive and multipotential cell, capable of developing into the other blood cells. This view, however, has been strongly contested by others, who have maintained that the small lymphocyte is a mature cell without any developmental potentialities whatever.

Defence Function of Lymphoid Tissue: Genetic Plasticity

If the lymphocyte cannot function as a primitive multipotential cell, is there any other function which we can assign to it? It has been thought to possess a defensive role, and in recent years it has been shown that many of the cells in lymphoid tissue can produce antibodies to foreign protein. This is a remarkable property, which probably involves genetic changes in the cells. It requires a primitive and undifferentiated cell, presumably, to be able to develop new secretions in response to new stimuli. It is not difficult to accept the view that such a cell, capable of producing on demand a variety of antibody globulins, should also be able to give rise to substances such as hæmoglobin.

Cell Transfusion Experiments

The lymphoid cells, as also those of the bone marrow, are very sensitive to radiation. Severe radiation will kill the great majority of these cells, and after a while death of the organism results. It can, however, be prevented by giving the animal an intravenous transfusion of cells from the bone marrow of a normal animal. The transfused cells colonize the bone marrow of the recipient, as has been elegantly demonstrated by transfusing cells with unmistakable biological markings. If the lymphocyte is a primitive cell, then lymphocyte transfusions should protect in the same way; but there are no convincing experiments to this effect.

Marrow transfusion experiments do, however, show that the marrow can take up cells from the blood stream rapidly and in large numbers. In such cases there is, furthermore, rapid regeneration of thymus and lymph glands. In all these instances the transfused cells function presumably as homografts, and if so it would follow that transfused marrow cells can colonize lymphoid tissues. In fact, if a small amount of marrow is shielded during severe irradiation, recovery of the animal and regeneration of its lymphoid tissues will usually follow.

Cellular Migration Streams in the Normal Animal

The trend of work in recent years has been to suggest that, through the blood, lymphocytes may stream in either direction between the lymphoid complex and the bone marrow, and also between the different parts of the lymphoid complex. The thymus may exert some chemical influence on the other members of the lymphoid complex, or it may send continuous cellular reinforcements to them. The blood appears to be the great pathway for all these cellular migrations from one tissue to another.

ELECTRICAL DOUBLE LAYER IN COLLOID SCIENCE

NEARLY one hundred physical chemists, from academic and industrial laboratories, attended a one-day informal discussion sponsored by the Colloid and Biophysics Committee of the Faraday Society and held on September 16 in the Chemistry Department of the Royal College of Science, London, at the invitation of Prof. R. M. Barrer and his staff.

The practical significance of electrokinetic effects was reflected in the wide range of materials which had been studied by different speakers—for example, polyelectrolytes in solution, dispersions of inorganic oxides or synthetic resins, oil-in-water emulsions stabilized by monolayers of detergents or macromolecules, organic salts in non-aqueous solvents (relevant to the paint and petroleum industries), a concentrated inorganic sol, and membranes of ion-exchange resins (similar to those now coming into use for electrodialytic de-salting of brackish water).

Four of the electrokinetic effects were discussed, namely, electrophoresis, streaming currents, electroviscosity and electro-osmosis; but it is recognized that these are equivalent experimental means of studying the mechanical properties of the electrical double layers which are to be found at almost all interfaces, and which are largely responsible for such widely different practical effects as, for example, the stability of soap emulsions, stickiness of clay soils, and the dangerous electrostatic charges sometimes encountered when petroleum products are pumped through metal pipes. The discussion, however, was concerned with fundamental problems of the origin and structure of double layers and the quantitative theory of their effects. These are by no means new problems; but as the chairman, Sir Eric Rideal, reminded the meeting, electrokinetic effects are among the easiest to detect and the most difficult to interpret.

Prof. J. Th. G. Overbeek and Dr. B. van Geelen (Utrecht) reported a comprehensive study of electrophoresis and electrical transport in solutions of polymethacrylic acid partially neutralized by sodium hydroxide and containing between 10^{-4} and 10^{-1} M sodium chloride. The mobility of the chloride ions is little affected by the presence of the poly-ions (from which, of course, they are repelled), but the mobility of the sodium counter-ions is low, particularly when the polymethacrylate ions are highly charged and the ionic strength is low; indeed, the majority of the counter-ions are then carried along with the poly-ions. The mobility of the poly-ions increases, as to be expected, with increasing charge, though less than linearly. Quantitative treatment of such effects in terms of current theories[1] of polyelectrolytes is only partially successful. Rather drastic refinements will have to be introduced into the theories. It was pointed out that in electrophoresis of polyelectrolytes the polymer coil is more nearly 'free-draining' than in sedimentation or diffusion because of the migration of the counter-ions through the coil.

Dr. P. J. Anderson (Atomic Energy Research Establishment, Harwell) surveyed recent studies[2] of dispersions of several inorganic oxides (for example, the dioxides of titanium, zirconium and thorium) in dilute inorganic electrolytes. The electrophoretic velocities of the particles were translated into ζ-potentials and electrokinetic charge densities (σ) by use of the standard Gouy–Chapman theory and its modern refinements for electrophoresis (Henry, Overbeek). The values of σ, regarded as due to adsorption of ions from solution on to an inert surface, provide an adsorption isotherm which is generally of the Langmuir form, and the constant of the isotherm is a measure of the adsorbability of the ions. The usual effects of ion valence are found with the oxides, provided allowance is made for specific (chemical) effects of lattice ions, and the order of adsorbability in a series of ions of given valence can often be correlated with their polarizabilities, etc. An outstanding problem is why saturation of adsorption, calculated from the isotherms, would correspond to only about 1 ion per 1000 A.^{2} of surface, or 1 per cent of the surface available. If the adsorption model is a valid interpretation of electrokinetic data for such surfaces, the results suggest that adsorption occurs only on special sites—perhaps point defects or dislocations.

Dr. D. A. Haydon (Imperial College of Science and Technology, London) discussed the results of a critical investigation of the interface between petroleum ether and solutions of sodium dodecyl sulphate and dodecyl trimethylammonium bromide in water, with and without excess sodium chloride. The surface charge densities (σ) of adsorbed detergent were determined from measurements of interfacial tension by application of the Gibbs equation (in its appropriate forms). From these results a surface potential (ψ_r) was calculated, assuming a Gouy-type diffuse double layer of counter-ions, but with allowance for the size of the ions. Stern adsorption, on the available independent evidence, was considered unlikely in this system. The ψ_r-potentials so obtained were in reasonable agreement with phase-boundary potentials determined directly by a vibrating-plate electrometer, though the latter were slightly lower with substrate concentrations above 0·01 *M*, suggesting that a small proportion of the counter-ions penetrates between the detergent ions. A striking difference, however, was found between the ψ_r-potentials and the ζ-potentials determined by microphoresis; ζ was always less than ψ_r, often less than $\frac{1}{2}\psi_r$. Furthermore, changes of ζ and ψ_r did not necessarily follow one another in sign; in the presence of excess sodium chloride ζ passed through a maximum with increasing concentration of anionic detergent, whereas ψ_r showed no maximum, nor was a maximum exhibited by the cationic detergent. These results seem to point to the conclusion that only a fraction of the diffuse double layer is sheared off in electrokinetics, the 'plane of shear' depending on ψ_r and on charge density, which perhaps cause some modification of the properties of water in the vicinity of the fixed monolayer. In discussion, Prof. Overbeek mentioned calculations which suggest that water might be immobilized in that part of the double layer where the field strength is greater than about 500,000 V. cm.$^{-1}$.

These ideas were supported by Dr. J. A. Kitchener and Dr. J. H. Schenkel (Imperial College of Science and Technology, London), who had made electrophoretic measurements in the course of studying the stability of a model suspension consisting of 10-μ spheres of surface-sulphonated polydivinyl benzene resin. The surface charge density of ionizing —SO_3H groups, determined by ion-exchange, was of the order of 10^5 e.s.u. cm.$^{-2}$, but σ calculated from the mobilities was only around 2×10^3 and, surprisingly, increased with addition of indifferent electrolyte. Since adsorption of co-ions on this highly ionogenic surface seems most unlikely, the results suggest a variable plane of shear in electrophoresis, an idea which was supported by the observation that ζ was reduced by addition of a non-ionic polymer. However, the system is complicated by the polyelectrolyte character of the surfaces, and Dr. D. C. Henry (Manchester) mentioned that in recent measurements of the surface conductivity of a similar material he had obtained much higher values than any previously reported for this quantity and suggested that a correction for the influence of surface conductivity might remove some of the anomalies.

Dr. H. W. Douglas (Liverpool) reported an investigation of the electrophoresis of a synthetic polycarboxylic acid having a hydrocarbon–ester backbone and an equivalent weight of about 250. This polyelectrolyte was studied in free solution in a Tiselius apparatus and also adsorbed on oil droplets (by the microscopic method). The mobility increased with *p*H from 2 to 6 and remained constant from 6 to 9; it decreased with increase of ionic strength. It was remarkable that the mobilities of the poly-ions were very similar to those of the coated droplets. (Prof. Overbeek confirmed this also for polymethacrylic acid.) The surface charge density at high *p*H was estimated to be around 50,000 e.s.u. cm.$^{-2}$, which was five to ten times that found by electrophoresis. Again a strong retention of counter-ions near the poly-ion is indicated. Furthermore, σ calculated from electrophoresis was found to increase with increasing concentration of sodium chloride at, for example, *p*H 9.

A paper by Prof. A. J. Rutgers (with Drs. M. de Smet and W. Rigole, of the University of Ghent) on streaming currents with non-aqueous solutions provided a glimpse of a different aspect of electrokinetics[3]. Prof. Rutgers described new results for solutions of tetra-*iso*-pentile ammonium-picrate in benzene (0–1,000 μmole/l.) streaming through long capillaries of various widths, wide capillaries of various lengths, a cylindrical slit or a system of closely fitting glass rings. Under some conditions, turbulence occurred with a consequent non-linear increase of the streaming current with increase of pressure. The currents were very small (10^{-13}–10^{-11} amp.) and special precautions were taken to collect them without loss. High ζ-values (for example, −280 mV.) were obtained with dilute solutions provided the capillaries were wide enough to exceed the thickness of the double layer, and long enough to exceed the value $V\tau$, where τ is the time of relaxation of the solution and V the mean velocity. A quantitative treatment of the effect of length and width of the tube has been developed, with allowance for the current carried by conduction and convection and by the glass itself. As predicted from the equations, a potential of several volts can be detected with dilute solutions flowing through a glass capillary.

Dr. R. H. Ottewill (Cambridge) reported work on the electro-viscous effect which he had carried out with Prof. Overbeek at Utrecht[4]. The effect is the apparent enhancement of viscosity observed in colloidal solutions or suspensions owing to the presence of electrical double layers around the particles. (With solutions of polyelectrolytes another factor, the expansion of the macromolecules, is sometimes also included under the term 'electroviscous effect'.) The system studied was a concentrated sol of silver iodide. The volume concentration and total electrolyte concentration were varied, and the apparent viscosity determined in a capillary viscometer at mean shear rates ranging from 200 to 2,000 sec.$^{-1}$. At high concentrations of electrolyte the viscosity was practically Newtonian and could be accounted for by purely hydrodynamic interaction between the suspended particles. In dilute solutions of electrolyte a strong electroviscous contribution enhanced the viscosity. Furthermore, the viscosity decreased with increasing rate of shear. The effects can be understood in terms of interaction between the diffuse double layers of neighbouring particles: at high rates of flow the counter-ion cloud becomes elongated and therefore interacts less with that of particles in adjoining flow lines.

The final two papers were concerned with a very different system, namely, membranes of ion-exchange resin. Electro-osmosis in such resins was first proved by the observation that their electrical conductivity is significantly higher than can be accounted for by the intrinsic mobility of the mobile ions ('internal counter-ions'), as determined by measurements of self-diffusion. It is clearly demonstrated by the fact that the passage of an electrical current through the material transports water in the direction of movement of the counter-ions. The system differs from the capillaries and porous plugs of classical electro-osmosis in that the solid wall is here replaced by a cross-linked polymer network and the inter-chain distance is not much greater than the mean distance of spread of the counter-ions from the chains. Despite superficial differences, therefore, this system has certain similarities to the polyelectrolytes considered in earlier papers in the discussion.

Drs. D. Mackay and P. Meares (Aberdeen) reported systematic studies[6] of electrical conductivity and electro-osmotic water transport through a highly swollen membrane of a phenolsulphonic acid resin in sodium form and in equilibrium with sodium chloride solutions of 0·01–1 *M* sodium chloride at 15°, 25° and 35° C., and also with mixed sodium and hydrogen forms of resins at two concentrations of electrolyte. These results were interpreted in conjunction with those previously obtained for the self-diffusion of sodium and chloride ions through the same resins. It appears that the conductivity of the sodium form of the resin in contact with very dilute solutions is simply equal to the sum of the ionic mobilities and electro-osmotic velocity; but at higher concentrations the conductivity is lower than that calculated in this way. It was suggested that this might be due to decreasing electro-osmotic velocity and particularly to its effect on the mobility of co-ions, which apparently have a different migration mechanism from the counter-ions. The velocity of electro-osmotic streaming of solution through the membrane was found to be proportional to the potential gradient.

In contrast to this result, Drs. G. J. Hills, P. W. M. Jacobs and N. Lakshminarayanaiah (Imperial College of Science and Technology, London) reported that they had repeatedly observed that the volume of solution electro-osmotically transported per faraday increased with decreasing current density in the range below 20 m.amp. cm.$^{-2}$: the effect seemed to be well outside the experimental errors. However, at higher current densities the anomaly disappeared. Measurements on membranes of polymethacrylic acid and phenolsulphonic acid in equilibrium with dilute aqueous solutions of the chlorides of lithium, sodium, potassium, rubidium and cæsium were reported. Water-transport was a little greater with lithium than with cæsium, but considerably greater in the phenolsulphonic acid membrane than in the polymethacrylic acid (for example, 28 moles of water per mole of sodium ion in the former, compared with 11 in the latter). Part of this water might be carried in a solvation sheath and the remainder by 'electro-convection', that is, by flow of the internal solution. However, attempts to separate the two by calculating a mean electro-convective velocity from a combination of electrical conductivity and self-diffusion coefficients, using the Nernst–Einstein equation, have not been encouraging. The difficulty probably arises from the non-uniform composition of the mobile medium inside the internal diffuse double layer. In this system, therefore, as in electrophoresis, a more precise model of the double layer seems to be called for if a quantitative treatment of the electrokinetic effects in terms of structure is to be achieved.

Dr. Hills emphasized in a discussion with Prof. Rutgers that he did not think that a classical electrokinetic approach to transport in ion-exchange membranes was appropriate.

THE YARD AND THE POUND (AVOIRDUPOIS) FOR SCIENCE AND TECHNOLOGY

THE directors of the following standards laboratories have discussed the existing differences between the values assigned to the yard and to the pound in different countries: Applied Physics Division, National Research Council, Ottawa, Canada; Dominion Physical Laboratory, Lower Hutt, New Zealand; National Bureau of Standards, Washington, United States; National Physical Laboratory, Teddington, United Kingdom; National Physical Research Laboratory, Pretoria, South Africa; and National Standards Laboratory, Sydney, Australia. To secure identical values for each of these units in precise measurements for science and technology, it has been agreed to adopt an international yard and an international pound having the following definitions: the international yard equals 0·9144 metre; the international pound equals 0·453 592 37 kgm.

It has also been agreed that, unless otherwise required, all non-metric calibrations carried out by the above laboratories for science and technology on and after July 1, 1959, will be made in terms of the international units as defined above or their multiples or submultiples.

The new international units conform with the recommendations of the Board of Trade Departmental Committee on Weights and Measures Legislation (the Hodgson Committee), but the Board of Trade points out that the units will have no statutory force and may not be used for trade purposes in the United Kingdom. The yard and pound units to be used in trade are the imperial units laid down in the Weights and Measures Act, 1878.

The values of the yard currently in use in the British Commonwealth and the United States of America are as follows, when expressed in terms of the metre: 1 imperial standard yard = 0·914 397 2 metre; 1 Canadian yard = 0·9144 metre; 1 yard as at present used by the National Physical Laboratory for science and technology, based on the 1922 value of the imperial standard yard = 0·914 398 41 metre; 1 United States yard = 0·914 401 83 metre.

As the imperial standard yard is about 5 parts per million (0·0002 inch) less than the United States yard (which is defined in terms of the metre) and is shortening at the rate of more than one-millionth of an inch per annum, the consequent discrepancies in measurements of length are important in modern precision engineering. To give two examples, it is necessary to know the lengths of the highest grade block gauges accurately to one part per million, and the permissible error on accurate yard scales is 0·0001 inch. Though the National Physical Laboratory, by using the metre and wave-lengths of light and by adopting the 1922 value of the imperial standard yard in relation to the metre, has been able to stabilize its basis of reference for length measurements in terms of the yard and its common sub-multiples for science and technology, unification of the yard standard for these purposes in the British Commonwealth and the United States can no longer be delayed.

With regard to the pound, the values currently in use when expressed in terms of the kilogram are: 1 imperial standard pound = 0·453 592 338 kgm.; 1 Canadian pound = 0·453 592 43 kgm.; 1 United States pound = 0·453 592 4277 kgm.

There is evidence that the imperial standard pound has diminished by about 7 parts in 10 millions since 1846. It is about 2 parts in 10 millions (0·0014 grain) smaller than the United States and Canadian pounds, which are defined in terms of the very closely safeguarded international prototype kilogram. Though the discrepancy between the pounds is not at present causing any technical difficulty, the co-existence of independently defined pounds is unsatisfactory in science and technology.

The agreed international values of the yard and the pound fall between the existing United States and British units, and the international yard, which is the same as the Canadian yard, accords exactly with the relationship 1 inch = 25·4 mm., which is already extensively used in Great Britain and abroad for approximate conversions. The adoption of the international values of the yard and the pound will be of particular benefit to all those concerned with accurate measurements of length and mass for scientific and technological purposes in the British Commonwealth and the United States.

OBITUARIES

Dr. John Jackson, C.B.E., F.R.S.

Dr. John Jackson died in Epsom Hospital on December 9 at the age of seventy-one. His interest in astronomy was aroused when he studied under Prof. Ludwig Becker at the University of Glasgow. There he received a thorough grounding in celestial mechanics and in spherical astronomy. From Glasgow he proceeded to Trinity College, Cambridge, and was placed among the Wranglers as a result of the Mathematical Tripos Examination in 1912 and was awarded the Tyson Medal and Sheepshanks Exhibition. In 1914 he received the first Smith's Prize.

His attention was directed to the problem of retrograde satellite orbits and, in particular, to the motion of Jupiter's eighth satellite. This satellite had been discovered by Melotte at the Royal Observatory, Greenwich, in 1908. It was the first satellite of Jupiter with a retrograde motion to be discovered and, because of the perturbing action of the Sun, its movement is very complicated. Observations of this satellite are difficult to obtain and are few in number, so that its orbit is even now rather uncertain. In 1914 Jackson was awarded the Mackinnon Studentship of the Royal Society for research on the motion of this satellite, but shortly afterwards he was appointed chief assistant at the Royal Observatory, Greenwich. He remained there for nineteen years and, during that time, he entered fully into all the programmes of observation that were undertaken.

His first important work at Greenwich was concerned with the observations of binary stars that had been made there with the 28-in. refractor over a period of many years. These observations had been published in the annual volumes of Greenwich Observations, but no use had been made of them. He determined the orbits of a number of these binary systems, and combined the observations made at Greenwich with those that had been made elsewhere. For many of the systems, the periods of which were long, observations have not been extended over sufficient years for orbits to be derived; but the observations of these systems were used to infer their parallaxes and Jackson derived the hypothetical parallaxes of 556 systems.

In 1924 the Shortt free-pendulum clocks were introduced at the Observatory as the standards of time, replacing the regulator clocks that had previously been used. Jackson, in conjunction with W. Bowyer, discussed their performance and showed that, as a result of the nutation of the Earth's axis, sidereal time was not uniform. As a result of these investigations, astronomers have since had to distinguish between apparent and mean sidereal time. Jackson looked into the possibility that the accurate time-keeping of these clocks might provide information about the variability in the rotation of the Earth, but concluded that they were not sufficiently accurate to give trustworthy determination of the variability.

Another important piece of work, undertaken in collaboration with Dr. H. Knox-Shaw, the Radcliffe Observer at Oxford, and his assistant, Mr. Robinson, was a careful reduction of the observations of the Sun, Moon, planets and stars, which had been made at the Radcliffe Observatory, Oxford, during the years 1774–98 by Hornsby. These observations had not been reduced and, for their epoch, were of high accuracy. Such early positions of these bodies are of value in connexion with the determination of the proper motions of the stars, and the investigation of the orbits of the Sun, Moon and planets.

In 1933 Jackson was appointed H.M. Astronomer Royal at the Royal Observatory, Cape of Good Hope, and held that position until his retirement in 1950, when he returned to Great Britain to take up residence. The Cape Observatory has a long tradition of accurate meridian and astrometric observations. The principal programmes of observation undertaken during Jackson's tenure of office were fundamental meridian observations with the Gill transit circle, the determination of positions and proper motions of stars, the determination of parallaxes of southern stars and the preparation of a photographic catalogue of southern stars between 30° S. and the South Pole.

Under his direction, Dr. R. H. Stoy, who, on Dr. Jackson's retirement, succeeded him as H.M. Astronomer, undertook the determination of the magnitudes of the brighter southern stars, which has established the photometry of the southern stars on a satisfactory and accurate basis.

During the Second World War the staff at the Observatory was much reduced, many members having left to undertake war-work of various sorts. Nevertheless, the output of observations continued at a remarkably high rate, Dr. Jackson himself being an assiduous observer.

Among his other interests was the observation of total eclipses of the Sun. While at Greenwich he obtained successful observations of the total eclipse of 1927 at Giggleswick and that of 1932 at Parent in Canada. He had also led an eclipse expedition to Alor Star, Kedah, Malaya, in 1929, when clouds unfortunately prevented observations being obtained. In 1940, when the War prevented the eclipse expedition from Greenwich proceeding to South Africa for the observation of the total solar eclipse in that year, the instrumental equipment was sent to South Africa, and under Jackson's direction the eclipse was observed under clear conditions at Calvinia in Cape Province.

Dr. Jackson was elected a Fellow of the Royal Astronomical Society in 1913 and served as secretary during 1924–29. After his return to Britain he was elected president of the Society for the period 1953–55. He was elected a Fellow of the Royal Society in 1938. He was president of the Commission on Meridian Astronomy of the International Astronomical Union during 1935–38, and president of the Commission on Parallaxes and Proper Motions during 1938–52. In 1952 he was awarded the Gold Medal of the Royal Astronomical Society for his work on stellar parallaxes and his contributions to the general problems of star positions and proper motions. Last year he was awarded the Gill Medal of the Astronomical Society of South Africa for his important contributions to astronomy during his period as H.M. Astronomer. He was made C.B.E. in 1950.

H. SPENCER JONES

Sir James Myers, O.B.E.

SIR JAMES MYERS, whose death was reported recently, had been associated with Manchester throughout his academic life. He was graduate in chemistry of Manchester, he served for a period as senior lecturer in chemistry and as secretary and tutor of the Faculty of Science of the University, and then, after a period as principal of the Manchester College of Technology, he was director of the School of Education of the University of Manchester.

Sir James was principal of the Manchester College of Technology during 1938–51—a period of very obvious difficulty. He had been a prominent member of the Faculty of Science in the University of Manchester, and it was hoped that he would consolidate relationships between the College as the Faculty of Technology and the rest of the University; instead, he was thrust into the hurly-burly of adaptation to the war effort. Under his guidance the College performed sterling work in both the educational and industrial fields.

There is little doubt, however, that he was not in his element in this sort of capacity; he preferred a slower-moving philosophical life. This was not to be, however. When the War ended, the College was one of the first university institutions to proceed with extensions, and the trials and tribulations of this activity again fell largely on his shoulders. It was not surprising that, in 1951, after receiving a knighthood for his services to technological education, he withdrew to the more peaceful pastures of the School of Education in Manchester.

I had the privilege of working under him for six years. He was a delightful person to know—full of warm humanity, of witty stories told with a strain of philosophy that left its mark, of wise advice to his subordinates. He was a gentleman in every sense of the word, and his influence on the College will be felt for a long time.

H. LIPSON

Dr. Kenneth W. Neatby

DR. KENNETH W. NEATBY, director of Science Service in the Canada Department of Agriculture, died on October 27. His death will be a very distinct loss to agricultural science and particularly to his own Service, which he has been directing for the past twelve years, and in which he was successful in building an effective research atmosphere. During the spring and summer of 1958, he had been instructed to take the lead in the formation of a Research Branch in the Canada Department of Agriculture through the amalgamation of Science Service and the Experimental Farms Service.

Dr. Neatby's career in research began with his appointment, in 1926, to the staff of the Dominion Rust Research Laboratory in Winnipeg. In addition to the actual development of varieties of wheat that were resistant to stem and leaf rust, he began a series of intensive studies of the inheritance of resistance to rust in wheat. Out of his work there came a much clearer understanding of the relation between the genes for resistance to rust and the various physiological races of the rust organism. This formed the foundation for work that is still going on and becoming increasingly valuable in our understanding of the cereal rust problem.

In 1935, Dr. Neatby went to the University of Alberta in Edmonton as head of the Department of Field Crops. This was perhaps the beginning of his intense interest in education, particularly for a research career in biology. His writings and addresses on this subject have undoubtedly had an important influence on the course of agricultural education and research in Canada. Some excerpts from an address given at Macdonald College are examples of his thinking: "The student who allows the laboratory to keep him from the library, thereby depriving himself of the influence of great men of the past in other fields of learning, as well as his own, may become a competent technician but he is unlikely to become an influential scientist." "We hear a lot about training for research, but surely this is either a contradiction in terms or a misapplication. Fruitful research depends on knowledge, imagination, ideas and dogged perseverance, not on techniques derived by formal training, essential as these may be."

During 1940–46, Dr. Neatby was director of the Farm Service of the North-West Line Elevators Association at Winnipeg. Here, he gained a first-hand knowledge of agricultural problems and became very conscious of the need for first-class research work in agriculture. From 1946 on, as director of Science Service, he built up an organization which has become very well known for its contributions in biology.

C. H. GOULDEN

NEWS and VIEWS

The Russian Artificial Planet

THE final stage of a Russian multi-stage rocket, launched at about 17.00 hr. U.T. on January 2, flew past the Moon to become the first artificial planet of the Sun. The final-stage rocket is stated to have weighed 1,472 kgm. (3,245 lb.) after all its fuel was burnt, and its pay-load of scientific instruments, together with the container, weighed 361·3 kgm. (797 lb.). The instruments were intended to measure the Moon's magnetic field, the intensity and composition of cosmic rays, lunar radioactivity, the impact of meteors and the composition of the Moon's atmosphere. The rocket was also equipped with radio transmitters operating on some or all of the frequencies 183·6, 19·997, 19·995, 19·993, 71·2 and 212 Mc./s. The programme of scientific measurements is stated to have been successfully accomplished before radio contact was lost on January 5.

The rocket left the Earth with a speed of 7 miles/sec., and when it was about 75,000 miles out, at 00.57 hr. U.T. on January 3, it emitted a cloud of sodium vapour which was observed from the Earth as a glow in the constellation of Virgo. By 10.00 hr. U.T. on January 3 the rocket was 130,000 miles from the Earth's surface, at longitude 40° W. and latitude 8° S. The rocket passed the Moon, at a distance of 4,700 miles from its surface, at 02.59 hr. U.T. on January 4 and was then moving at a speed of 1·5 miles/sec. away from the Earth. Since the Moon was near last quarter at the time of the launching, the rocket's path was nearly tangential to the Earth's orbit; the rocket's orbit around the Sun, therefore, has almost the same perihelion distance as the Earth's orbit, though the aphelion distance is greater, because of the rocket's greater speed at perihelion. Its orbit is inclined at only a small angle to the plane of the ecliptic and the distance from the Sun is expected to vary between a minimum of 91 million miles and a maximum of 122 million miles. The period of revolution will be about 450 days, with the first perihelion on about January 14.

New Year Honours

THE following names of scientists and others associated with scientific work appear in the New Year Honours list:

Baronet: Kenneth W. M. Pickthorn, during 1935–50 member of Parliament for the University of Cambridge, for political and public services.

C.H.: Sir John Beazley, emeritus professor of classical archæology, University of Oxford, for services to scholarship.

Knights: Prof. Alexander W. G. Ewing, director of the Department of Education of the Deaf, University of Manchester; Stuart Gillett, lately chairman of the Tanganyika Agricultural Corporation; Henry R. F. Harrod, University lecturer in economics, University of Oxford; Dr. Reginald P. Linstead, rector of the Imperial College of Science and Technology, University of London; Dr. Douglas W. Logan, principal of the University of London; Kelvin T. Spencer, chief scientist, Ministry of Power; Prof. Arthur P. Thomson, professor of therapeutics and dean of the Medical School, University of Birmingham.

K.B.E.: Albert E. Axon, chancellor of the University of Queensland, for public services; George W. H. Gardner, director of the Royal Aircraft Establishment, Farnborough (Ministry of Supply); Prof. Marcus L. E. Oliphant, director of the School of Research in Physical Sciences, National University, Canberra; Geoffrey S. Peren, principal of Massey Agricultural College, New Zealand; Sir George Wilson, chairman of governors, West of Scotland Agricultural College.

C.B.: Air Commodore R. H. E. Emson, director of air armament research and development, Ministry of Supply; W. B. Littler, director-general (scientific research (munitions)), Ministry of Supply; J. W. Stork, director of studies, Britannia Royal Naval College, Dartmouth; A. A. Part, under-secretary, Ministry of Education.

C.M.G.: T. H. Searls, lately director, Universities and Adult Education Department, British Council; Prof. H. C. Webster, professor of physics, University of Queensland, for services to the Federal Government of Australia.

C.B.E.: Dr. Muriel E. Bell (Mrs. Hefford), nutritionist to the Department of Health and superviser of Nutrition Research, Department of Medical Research Council, New Zealand; M. M. Burns, director of Canterbury Agricultural College, Christchurch, New Zealand; W. A. S. Butement, chief scientist, Department of Supply, Australia; Dr. M. Cook, chairman of the Metals Division, Imperial Chemical Industries, Ltd.; I. J. Cunningham, superintendent of the Animal Research Station, Wallaceville, New Zealand; Dr. I. de Burgh Daly, lately director of the Institute of Animal Physiology, Babraham, Cambridge (Agricultural Research Council); Capt. N. Fawcett, H.M. chief inspector of explosives, Home Office; P. T. Fletcher, deputy managing director, Industrial Group Headquarters, Atomic Energy Authority, Risley; T. A. Lang, associate commissioner, Snowy Mountains Hydro-Electric Authority, Australia; A. B. Lilley, medical director of the Cancer Council, New South Wales; S. C. Longhurst, lately a member of the Forestry Commission; R. A. Lovell, chief mechanical engineer, Ministry of Transport and Civil Aviation; Prof. W. T. J. Morgan, professor of biochemistry, University of London, and member of the Biological Research Advisory Board, Ministry of Supply; Dr. H. J. Plenderleith, keeper in the British Museum; Dr. E. E. Pochin, director of the Department of Clinical Research, University College Hospital Medical School (Medical Research Council); J. A. Ratcliffe, chairman of the Radar and Signals Advisory Board, Ministry of Supply Scientific Advisory Council, reader in physics, University of Cambridge; R. H. Schlotel, director of engine research and development, Ministry of Supply; R. B. Tennent, director of agriculture, New Zealand; Dr. H. W. Thompson, lecturer in chemistry, University of Oxford, senior regional scientific adviser for civil defence, Southern Region; Prof. S. J. Watson, professor of agriculture and rural economy, University of Edinburgh.

U.K. Atomic Energy Authority, Metallurgy Division: Mr. L. Grainger

Mr. L. Grainger has been appointed head of the Metallurgy Division of the United Kingdom Atomic Energy Authority's Research Group at Harwell. He is to succeed Dr. H. M. Finniston, who is being released by agreement to take up appointment with the Nuclear Power Plant Co. Mr. Grainger was born in Sheffield, in 1917, and was educated in Detroit but returned to England in 1933. He was in steel works until the War. He then joined the Admiralty and served with the Royal Air Force as fighter controller during 1943–47, afterwards returning to the Royal Naval Scientific Service to work on co-ordination of metallurgical research, particularly brittle fractures, creep testing, and development of new structural materials. He joined the U.K. Atomic Energy Authority in 1951, and later became head of Laboratories, Research and Development, Springfields. In 1955, he moved to Risley as chief metallurgist in the Research and Development Branch, becoming deputy director of research and development in 1958. He is the author of "Uranium and Thorium" (Newnes, 1958).

British Cast Iron Research Association:

Dr. J. G. Pearce, C.B.E.

Dr. J. G. Pearce, who has been director of the British Cast Iron Research Association since 1924, is to retire. During his tenure of the office he has seen the Association grow steadily both in size and importance. A graduate of the University of Birmingham, he has built up an international reputation and among other distinctions he has received the honorary doctorate of engineering of the University of Aachen. In 1957 he was made C.B.E. A member of the Worshipful Company of Founders, the Livery recently conferred on him its Founders' Medal for his services to the "art and mystery" of iron-founding. Before going to the British Cast Iron Research Association, Dr. Pearce was associated with Sir Arthur Fleming in the planning and organization of the Research and Education Department of the Metropolitan-Vickers Electrical Co., Ltd., and was co-author with Sir Arthur of two text-books on apprentice training and industrial research. He has served on many national and international committees and, since 1935, has, among other responsibilities, been chairman of the main committee on cast iron of the British Standards Institution.

Mr. H. Morrogh

Mr. H. Morrogh, at present deputy-director of the British Cast Iron Research Association, has been appointed to succeed Dr. J. G. Pearce as director. Educated at the George Dixon Grammar School, Birmingham, he joined the Association's staff in 1933 and became research manager in 1945. His main work, for which he has received international recognition, has been in connexion with the microstructure of cast irons, and in particular the identification of inclusions and the formation of graphite. It was from the latter work that the discovery of nodular graphite iron, perhaps the most important discovery ever made so far as this material is concerned, was announced in 1948. These contributions have been recognized by the award of gold medals by the Iron and Steel Institute, the Institute of British Foundrymen and the American Foundrymen's Society. He speaks with absolute authority in his own field, and although he himself received no university training, Mr. Morrogh has persistently encouraged higher metallurgical education, not only in the universities but also in the colleges of technology.

Vincenzo Lunardi (1759–1806)

Vincenzo Lunardi, who was born two hundred years ago on January 11, 1759, at Lucca in Tuscany, is remembered for having introduced aerostation into Britain. Joseph and Jacques Montgolfier constructed the first fire balloon, in which a sheep, a cock and a duck ascended on September 19, 1783. The first aeronaut in France was Pilâtre de Rozier later that year, and the first in Scotland was James Tytler on August 27, 1784. On September 15, 1784, on the Artillery Ground at Moorfields, the physician-chemist, George Fordyce, inflated a balloon, 33 ft. in circumference, with hydrogen before some 200,000 impatient spectators. Its passengers were a pigeon, a dog, a cat and Lunardi, who was secretary to Prince Caramanico, the Neopolitan ambassador. Lunardi had arranged to take an Englishman with him, but as there was insufficient hydrogen to sustain the extra weight, he was compelled to go alone. The balloon was provided with oars intended to raise or lower it at will, but one oar broke and fell to the ground. After 1½ hr. Lunardi descended at South Mimms in Hertfordshire to land the cat, which had suffered from the cold—the pigeon had already escaped—and made a second descent three-quarters of an hour later near Ware, having drifted twenty-four miles. This exploit excited enormous enthusiasm, and the balloon was exhibited for profit at the Lyceum in the Strand. In the following year Lunardi made several successful ascents from Kelso, Edinburgh and Glasgow. His letters to his guardian, Chevalier Compagni, which were published, contain a vivid account of his pioneer ventures. A strikingly handsome man, Lunardi died on July 31, 1806, at the age of forty-seven.

Building Research

The Lord President of the Council and the Minister of Works have decided that the Department of Scientific and Industrial Research should in future be the only Government department with responsibility for building research. Hitherto, the Ministry of Works has shared this responsibility through the Advisory Council on Building Research and Development. This Council, which was set up in 1947, and has made a most valuable contribution to the whole field of building research, will therefore not be continued after its present two-year period expires in March. To ensure continuity of the work previously undertaken by the Advisory Council, the Department of Scientific and Industrial Research will invite the various sections of the building industry to nominate representatives to a Standing Conference on Building Research and Development. The Ministry of Works will continue to provide the present service of advisory leaflets, lectures and the technical information service.

United States Atomic Energy Commission Charges for Uranium-233 and Plutonium

The United States Atomic Energy Commission has established the charges at which uranium-233 and plutonium will be made available for use in research and development to private individuals and companies in the United States and to foreign governments under agreements for co-operation, at

15 dollars per gram of uranium-233 and 12 dollars per gram of plutonium. While the charges are subject to change, it is the Commission's intention to keep them as stable as possible. In the United States uranium-235, uranium-233 and plutonium may be owned only by the Government, and may be made available for private uses only on a lease basis. The annual lease charge will be 4 per cent of the basic charge. These nuclear materials may be either sold or leased to foreign governments, and are available to those governments having agreements for co-operation with the United States. The charges announced will also apply to material distributed abroad. Research and development on uranium-233 and plutonium are generally in connexion with their use as reactor fuels. For this reason the charges are set at levels representing the fuel value of uranium-233 and plutonium as compared to existing charges for uranium-235, the material used as fuel in most reactors. The allotment for domestic civilian use totals 3·6 kgm. of uranium-233 and 37·5 kgm. of plutonium. Present allocations to domestic licensees amount to 0·04 kgm. of uranium-233 and 12·12 kgm. of plutonium, with applications for additional amounts pending. A study is in progress to determine what additional quantities should be made available for these purposes.

Pollution from Power Station Chimneys

When a wet fog lasts for many hours, the loss of heat by radiation into space from the top causes downward convection currents which stir the whole volume of the fog. At the top there is a sharp temperature inversion, the air immediately above the fog being warmer than the fog layer. Most pollution emitted within the fog remains within it, and if the fog is stagnant, the concentrations of smoke and sulphur dioxide may rise to dangerous magnitudes. It is therefore of the utmost importance to know whether the hot gases from a power-station chimney rise out of the top of the fog or are trapped below the inversion and contribute substantially to the accumulation of pollution below. Theoretically, the problem poses difficult questions which have not yet been overcome, and all theories are bound to make one or more assumptions which cannot be justified except by a long series of observations or experiments which have not yet been performed. The Central Electricity Generating Board has employed Fairey Air Surveys, Ltd., to fly over, and in, shallow London fog to measure temperatures and observe the behaviour of plumes from power stations along the Thames. The considerable navigational problems have been overcome, and on the morning of December 4 a flight was made and the plumes from three Thames-side stations were observed to rise into, and remain in, the air above the fog layer. The plumes from Brunswick Wharf Power Station were coloured red and black so that identification was certain, and photographs taken show that on this occasion the power stations did not contribute at all to the pollution at ground-level. There are undoubtedly circumstances of deeper fog and stronger inversions when the plumes would be contained in the fog layer. Further observations and experiments will be required before these circumstances can be specified with confidence; but it is clearly possible to build chimneys high enough and emitting gases hot enough for the gases to escape into the air above, and not contribute their quota of sulphur dioxide to the air we breathe at the ground when stagnant fogs occur.

Technological Education in India

Sir Willis Jackson, director of research and education, Metropolitan-Vickers Electrical Co., Ltd., has accepted an invitation from the Ministry of Scientific Research and Cultural Affairs of the Government of India to act as chairman of a committee, set up by the President of India, to review the work and progress of the first of the technology institutes in that country, namely, the Indian Institute of Technology, Kharagpur. The committee includes Shri D. L. Deshpande, director of the Bihar Institute of Technology; Dr. Atma Ram, director of the Central Glass and Ceramic Research Institute; Prof. M. Mujeeb, vice-chancellor of Jamia Millia Relamia, Okhla; Shri S. Ratnam, former finance secretary of the Government of India; and Shri G. N. Vaswani, assistant educational adviser (technical) of the Ministry, who will act as secretary.

Exchange of Students for Technical Experience

The eleventh annual report of the International Association for the Exchange of Students for Technical Experience (pp. 71. London: 1958) records in 1958, for the first time since the foundation of the Association, a decrease in the number of participants —from 5,934 in 1957 to 5,394 between 24 member countries. On the other hand, 2,777 industries, etc., participated, 436 universities and colleges, covering forty faculties, compared with 2,761 industries and 401 universities in 1957. Great Britain sent 774 students and received 784; for Sweden the corresponding figures were 359 and 736; France 343 and 410; Canada 24 and 95; Switzerland 151 and 202; Finland 175 and 202; and for Germany 998 and 1,023. Of those countries sending more students than they received, Austria sent 562 and accepted 308; Yugoslavia 220 and 116; the Netherlands 446 and 370; Turkey 232 and 166; Spain 244 and 207; Italy 177 and 153; and Israel 97 and 60. A special evaluation made by Great Britain on the basis of 4,249 reports on students since 1949 is to be published shortly, and the Association believes that, so far as the exchange can be evaluated with statistics, it has proved an undoubted success.

Scholarships in Mathematics for Courses in Statistics and Computational Methods

The London School of Economics and Political Science is developing courses in statistics and computational methods within the general framework of the degrees in economics of the University of London. The object of the new arrangements is to equip graduates with specialized knowledge in certain mathematical subjects and a general appreciation of the wider field of economics including accounting. A number of industrial and commercial undertakings have promised generous support to enable the School to provide the technical equipment necessary for the proposed course of study. It has also enabled the foundation of scholarships tenable in connexion with the new course. Each scholarship will be worth £450 a year and will normally be tenable for three years. Awards will be made without regard to the income of the parents or guardians of the successful candidates. For the academic year beginning in October 1959, two scholarships will be available. Further information can be obtained from the Registrar, London School of Economics and Political Science, Houghton Street, Aldwych, London, W.C.2. Completed applications should be returned to the Registrar not later than January 31.

Interdisciplinary Conference on Self-Organizing Systems

An Interdisciplinary Conference on Self-Organizing Systems will be held on May 5 and 6 at the Museum of Science and Industry, Chicago, Illinois. The conference is to be co-sponsored by the Information Systems Branch of the Office of Naval Research and the Armour Research Foundation. The purpose of this conference is to bring together research workers in all fields of science who are concerned either with the development of self-adaptive information systems or with the conduct of research which may contribute to an improved understanding of cognitive, learning, and growth processes. Particular emphasis will be placed on theoretical models of systems which are capable of spontaneous classification, identification and symbolization of their inputs. Further information can be obtained from Mr. Scott Cameron, Conference Secretary, Armour Research Foundation, 10 West 35th Street, Chicago 16, Illinois.

Centenary of the Royal Society of Victoria

To mark the publication of Darwin's "Origin of Species" in November 1859, and the granting in the same month of the royal title to the Royal Society of Victoria, Australia, this Society will hold a symposium on "The Evolution of Living Organisms" during December 7–11, 1959. Dr. Ernst Mayr, of the United States, will be the principal speaker, and the symposium will open with a Tiegs Memorial Lecture in memory of Prof. O. W. Tiegs.

University News: Belfast

The following appointments have recently been made in The Queen's University of Belfast: G. C. R. Carey, to a lectureship in preventive medicine; Dr. G. S. Higginson, to a supernumerary lectureship in physics.

London

The title of reader in the University of London has been conferred on Dr. D. D. Davies (in plant biochemistry) in respect of his post at King's College; and on Dr. J. L. Mongar (in chemical pharmacology) in respect of his post at University College.

Pittsburgh

Thirty-two grants totalling 630,766 dollars have been awarded to the Division of the Natural Sciences of the University of Pittsburgh, Pennsylvania. Among the principal grants received since July 1, 1958, by six departments of the Division and the Radiation Laboratory are the following: 75,000 dollars to R. A. McConnell (assistant research professor, Department of Biophysics), from the A. W. Mellon Educational and Charitable Trust to continue research on psychological physics; 23,000 dollars to Dr. G. Felsenfeld (assistant professor, Department of Biophysics), from the National Science Foundation to initiate research on the active site in some copper-carrying proteins; 25,421 dollars to Prof. W. E. Wallace (Department of Chemistry), from the U.S. Atomic Energy Commission to continue an investigation of the application of chemical thermodynamics to study the formation of metallic alloys; 41,600 dollars to Dr. T. M. Donahue (associate professor, Department of Physics), from the Office of Naval Research to continue studies on capture-loss and ionization cross-sections of ions and neutral particles; 40,360 dollars to Prof. G. J. Wischner (Department of Psychology), from the National Institute of Mental Health to continue graduate training in clinical psychology; 129,000 dollars to Prof. A. J. Allen (director of the Radiation Laboratory), from the Office of Naval Research to continue research on precision scattering of nuclear particles; 38,415 dollars to Prof. G. A. Jeffrey (Radiation Laboratory), from the Air Force Office of Scientific Research to initiate research on the structure of crystalline hydrates of organic molecules and ions; 27,243 dollars to Prof. L. A. Page (Radiation Laboratory), from the U.S. Army Office of Ordnance Research to begin a research programme on low-energy nuclear and electron physics.

Announcements

Prof. Chien-Shiung Wu, professor of physics in Columbia University, New York, is to be awarded the 1958 Research Corporation Award for her valuable contribution to the knowledge of beta-decay and particularly for her part in research which resulted in the overthrow of the conservation of parity. She will receive an honorarium of 2,500 dollars, a plaque and a citation.

The following have been appointed to fill vacancies on the University Grants Committee: Dr. Kitty Anderson, head mistress, North London Collegiate School; Prof. Asa Briggs, professor of modern history, University of Leeds; Prof. F. A. Vick, professor of physics, University College of North Staffordshire; Dr. K. C. Wheare, rector of Exeter College, Oxford.

The symposium on "The Nature of Coal" organized by the Central Fuel Research Institute, India, will now be held during February 7–9, instead of during February 9–11, as was announced earlier (see *Nature*, 182, 295; 1958).

Between January 13 and March 17, the Department of Chemistry, Biology and Geology of the Kingston Technical College is holding a postgraduate lecture course on "Recent Advances in Protein Chemistry", with lecturers well known for their work in this field. Further information can be obtained from the Head of the Department at the Kingston Technical College, Fassett Road, Kingston-upon-Thames.

On February 6 the Scottish Branch of Aslib will hold its annual general meeting and conference in Glasgow. The theme of the morning session is patents, and that of the afternoon, mutual co-operation. The morning speakers will be Mr. Felix Liebesny on "Patents as Sources of Information", and Mr. Christopher Johnson on "Trade Marks and Industrial Designs, their History, Development and Protection". The afternoon speakers will be Mr. E. Martindale, of the Department of Scientific and Industrial Research, who will speak on the Scottish Research Laboratories Mutual Assistance Scheme, and, it is hoped, Prof. Christopher Macrae, from the Regional Technical Liaison Service of the Department.

In the communication entitled "Thermal Annealing of Chemical Radiation Damage" by Dr. A. G. Maddock and S. R. Mohanty in *Nature* of December 27, p. 1797, the graph refers to isothermal annealing at 150° C.

INDUSTRY AND THE INDIVIDUAL

THERE has been at least one remarkable change in British industry since the Second World War: that is the changed attitude towards the individual. Thirty years ago those discharged because of shortage of work were given short shrift; to-day, those unfortunate enough to be declared redundant are treated, in general, as individuals deserving sympathy, encouragement and help until they can become re-established.

To bring about this change in attitude has been one of the major pre-occupations of the Institute of Personnel Management, the membership of which has grown steadily in quantity and quality since the War. At Harrogate during October 10–12, the Institute held its most successful annual conference, which was attended by more than nine hundred representatives drawn from industrial organizations throughout the world.

The opening speaker was Sir Walter Puckey, chairman of Management Selection, Ltd., who argued that, of the many major industrial problems confronting us to-day, the four most pertinent are: the development of new 'machine' technologies; the development of new 'man' technologies; the development of men in the new machine age; the responsibility of the individual to the group and the group to society.

The State, backed by modern industry, is sponsoring more research per head per year than can be used economically, accepted socially, or desired militarily. This technological pressure is creating other pressures and problems, such as the financing of new projects, the need to double the numbers of technologists in ten years, the desirability of introducing more science into education, the greater need to humanize science, and the need to produce better political understanding in the face of a nuclear technological threat. Great success will attend those who encourage more laymen, arts men, workers, managers and scientists themselves to learn more of science and technology and so gaze with stimulated imagination and curiosity over the wider vista beyond.

Man is starting on a scientific exploration of himself, and recent years have seen an accelerated programme of research in physiology, psychology, neurology and sociology. Many leading industrialists are now convinced that an important field of research exists into individual man himself and his group relationships.

The better group objectives are organized the more likely is one to satisfy individual men within the group, but one should never be so committed to scientific method that one works towards, or desires, complete conformity. The better group management is, the more time and opportunity should be given to exceptional people and problems, remembering that while most men will conform most of the time, every man can and should be exceptional some of the time.

The development of social sciences and technologies is very important, but the greater use of the scientific approach to man and man-management will require better personnel management.

Thousands of skilled managers and millions of sensible workers have established in Britain a reasonable understanding with the machines of the first Industrial Revolution. We now have to establish a modified machine/man relationship in the second Industrial Revolution, where the machine will be more a machine of the brain than of the muscle. The brain machines may influence different groups of men, and their reactions may be even more critical than those of men in the first machine age.

The new machines will demand special skills which will be developed in, and used more by, the controlling or supervisory section of the working force. There has been a great invasion of offices by machines, and this will continue. We have seen the beginning of the impact of new machines and systems on control and communication activities, and their effect on organizational principles and practices. Since its birth, personnel management has been more concerned with blue or brown overalls than with white. The future may see a changing emphasis, with no less troubles in the first category but with added troubles in the second.

One important gap in the current research programmes will be filled when greater attention is paid to the problems of organizing men in the new machine environment. The installation and possibilities of a computer, for example, show how modern man can meet modern machines in a new and better relationship. There are far too many frustrations arising from poor organizational practices, and organization urgently calls for a more scientific approach. One way of judging a manager's effectiveness is his ability to delegate to other men. In the second Industrial Revolution one can also add his capacity to delegate to machines; this new man/machine delegation can create quite new organizational possibilities and problems.

The individual in the group and the group in society present two separate yet complementary problems. Individual recognition has been accorded to an increasing extent, from the level of Sir Winston Churchill to the growing number of occasions where individuality is recognized by placing names on badges at conferences, on desk signs in banks, stations, hotels and personnel offices.

Every indication of greater group power seems to be balanced by equal and opposite individual recognition. Currently, the technological developments in nuclear energy and automation are examples of this balancing factor.

As much attention has been given to human problems of safety in a nuclear age, and personal problems of living in an electronic brain age, as to the new technical problems themselves. It is significant that more books and major articles have been written on the Dead Sea Scrolls than on automation.

The problem of responsibility and efficiency in a nationalized industry was examined by Sir Harold Smith, chairman of the Gas Council.

The structure established by the Gas Act (1948) led to the setting up of twelve autonomous area boards. These are independent bodies for finance and tariffs, and are charged with the duties of developing and maintaining an efficient, co-ordinated and economical system of gas supply, and meeting, where economically possible, all reasonable demands for gas. The Gas Act also established the Gas Council, of which each area board chairman is a member. The Gas Council has a largely advisory relationship, not only with the Minister but also with each area board, and is charged with four specific duties relating to finance, research, training and education and industrial relations.

Through their association on the Gas Council, area boards are able to pool their specialized knowledge, skill and experience. As an example, research into the high-pressure gasification of small coals carried out at Solihull is to be developed commercially by the North Western Gas Board for the benefit of the whole industry.

In a public service industry, which has to maintain a continuous supply, it is essential to avoid stoppages through industrial disputes. There never has been a serious stoppage in supply. This is due to the co-operation of both employers and employees, fostered by the system of industrial relations in the industry. Both the employers and the trade unions concerned made an immediate response to the recommendations of the Whitley Committee, and the National Joint Industrial Council for the Gas Industry, together with its Regional (later Area) Joint Industrial Councils, dates from 1919.

The National Joint Industrial Council is still in existence, and the tradition of collective bargaining within the industry has been gradually extended by the creation of negotiating machinery to cover clerical staff, maintenance craftsmen, building trade workers, and ultimately all remaining groups of employees.

The statutory obligations imposed on the Gas Council and area boards, so far as industrial relations were concerned, were met largely by continuing the pre-vesting organization.

Joint consultation was encouraged in the industry before nationalization, and the National Joint Industrial Council had worked out a model constitution for works committees. The trade unions promised their support for the establishment of joint consultative committees at a joint conference on efficiency held in 1953, and such committees are now widely spread throughout the industry.

Improved efficiency since nationalization is shown by the use of fewer tons of coal to produce the same output. Additional costs including heavy capital charges have not been met by correspondingly increased revenue, the difference being absorbed by integration and higher efficiency.

Efficient organization is created largely through the individual efforts of its members. In the gas industry, the traditionally good industrial relations, and the emphasis on decentralization, encourage full participation by all employees.

The role of the trade unionist in relation to productivity and the rights of the individual were considered by W. J. Carron, president of the Amalgamated Engineering Union, who suggested that, although there have been isolated examples of 'go-slow' and other forms of direct action which have brought about alterations in the tempo and a retarding of productivity, ranging from restricted output, or service, to the extreme limit of total stoppage, at no time has trade unionism opposed or sought to obstruct productivity. The 'strike', the 'go-slow', the 'working to rule', or the 'overtime embargo' is merely the outcome of dissatisfaction with conditions of employment, a defence of the rights of an individual or group of individuals.

What are the rights of an individual when examined through the eyes of an industrialist as distinct from the objective approach of a social reformer ? It is difficult to segregate these two lines of theory because our social lives are inextricably interwoven with our industrial existence. The 'rights' of a modern worker in industry are not really 'rights' at all. They are mostly compulsory regulations laid down in the Factory Acts and similar statutory requirements which govern the employment of work-people. The remainder are to be found in agreements between trade unions and employers' organizations, both of which maintain a jealous watchfulness over the permissive and non-permissive clauses contained therein.

The formal establishment of an industrial 'right' dispossesses the individual in so far as that 'right' becomes the property of the nation or, to a less degree, of the particular pressure group that has succeeded in forcing its acceptance. The 'right' then stands every chance of becoming a 'must' and the individual has gained an industrial victory at the expense of industrial freedom.

There is no inconsistency in the desire of trade unions and trade unionists to make the closed shop more effective.

In highly complex industrialized societies it is necessary that certain personal freedoms must be limited to provide the greatest good for the greatest number. The character of our industrial pattern is such that there would be extreme difficulty in operating in a highly industrialized society without collective bargaining. For the maintenance of standards consistent with the rights of human beings it has been shown that trade unions are a necessary part of an advanced society. There is a distinct and direct charge upon individuals to sustain those institutions which provide not only for their welfare but for their existence. It is morally wrong that individuals should obtain both directly and indirectly the benefit of trade unions while completely evading their obligations.

There is an obligation upon employers to take some interest in this question. The theory by employers that membership of trade unions is no business of theirs is an outmoded thought and an evasion of responsibilities.

The trade unions are constantly faced with the problem of what will happen to the people displaced if completely automated forms of production become more widely adopted.

The major right of work-people in a time of technological change is security through continued employment.

All other demands of work-people are conditional upon the fundamental requirement of employment and fair wages. Among them is the strong ambition to have some voice in the practical administration of the aims and purpose of the employing organization.

During the War, production committees were formed ; many have disappeared. Much could be done to expand the nature and the beneficial influence of such committees, to create a greater understanding of the difficulties and mutual problems affecting both sides of worker/management relationship.

As workers and citizens, trade unionists demand the right to industries equipped with modern methods of applied technology in production at least commensurate with those of international competitors. Trade unionists also demand the right to produce adequately trained personnel, who are able to justify the setting up of this modernized equipment. Trade unionists demand the right to see industries linked firmly and securely to universities, not only in terms of technical education but also for industrial research. The right of an individual to expect advances in his living standards, or even to expect to maintain them at their present level, must depend upon his willingness to co-operate in productivity.

Besides the main addresses at the Conference a number of sectional meetings were held to discuss topics like the closed shop, the development of sandwich courses, liberal education and technical training, the recruitment and training of young workers and the cost and changing place of fringe benefits in salary and wage agreements. The latter was addressed by J. Simons, a director of the Package Sealing Co. (Export) Ltd., who showed how the term 'fringe benefits' is one that has crept into industrial jargon in recent years to describe all those items other than hard cash in the pay packet which are of tangible value to employees, whether they cost real money or not to the employer. Two main factors which have brought about this situation are: the influence of taxation on earnings, and competition for labour in the period of full employment that has existed since the War. The first factor has had particular effect on the value of benefits attached to appointments at high executive level where tax becomes heavy. At these levels the provision of supplementary or 'top hat' pension schemes, substantial life assurance, education grants, and even the provision of housing, become important items in the total assessment. The second factor, competition for labour, accounts for the fact that initiative to add to fringe benefits has tended to come from management, rather than from trade unions, though the latter have brought pressure to bear on a number of factors, particularly holidays with pay, compensation for redundancy, guaranteed work-week, and in more recent years, pensions.

Though the provision of fringe benefits has grown in the past twenty years, it is still seldom that one finds them mentioned specifically in employment agreements as part of the contract of employment, even for executive appointments, and still less at operative-levels. Items within the field of fringe benefits are beginning to feature more and more in negotiated agreements between unions and selected industries.

In examining the costs of fringe benefits a number of aspects have to be considered. No clear picture has yet emerged on the correlation between the size of the company and the cash value per employee of the benefits provided; there is, however, some indication that the larger the industrial unit the greater is the range—and hence the cost per employee—of the benefits available.

One survey covered some sixty companies of varying size. It directed attention to the wide variation in the cost of certain items (pension, sick pay, life insurance, canteen subsidies and travelling allowances). For these items, the variation in cost among the companies covered by the survey was as follows:

Percentage of companies covered by the survey	Cost of all fringe benefits as per cent of total pay-roll
9	under 2½
14	2½–5
28	5–10
18	10–20
12	20–30
3	over 30
16	not disclosed

A more recent survey covering some fifty companies showed that the total cost of benefits varies between 12 and 25 per cent of the total employee remuneration —the median being just under 15 per cent.

In those cases where the cost is high, the biggest single item is usually pension contributions; it is here that many companies could secure better value for their money than they do. Those concerns that have made a close study of the provision of pensions, and have established internal funds with wide investment powers, are better placed to keep pace with inflation than those with insured schemes, and usually at lower cost.

The way to control 'fringe benefit' costs might be to predetermine an overall cost factor expressed as a percentage of the pay-roll, and from the proceeds to cover the costs of those benefits which the company, as a matter of good business policy, would wish to provide, leaving the residue to be used on additional benefits of the employees' own choice. It would have the merit of creating in the minds of both employers and employees a greater awareness that the provision of benefits costs money and that such costs require to be controlled. Such an arrangement would have the merit of controlling the costs of benefits in the simplest possible way; it would take them out of the realm of miscellaneous overheads and enable them to be treated as a definite cost item in the same way as wages and salaries.

MEASUREMENT AND CONTROL IN ELECTRICAL ENGINEERING

THE ever-widening interests and knowledge of electrical engineers as a body have their effects on the organization and division of the activities of the Institution of Electrical Engineers. Originally founded as the Society of Telegraph Engineers in 1871, it soon became necessary to indicate its wider interests by a change of name, first to the Society of Telegraph Engineers and Electricians in 1880 and then in 1888 to the Institution of Electrical Engineers.

Later it became necessary to make administrative provision for the presentation of specialist papers, and the Meter and Instrument Section came into being in 1928. Like its parent body, the interests of this specialized Section widened year by year, and its name was changed first to the Measurement Section and later to the Measurement and Control Section.

The most recent change is the institution of five panels concerned with particular aspects of the activities of this Section. Mr. J. K. Webb, in his address as chairman of the Section, delivered at the Institution on October 4, has most appropriately directed attention to recent technical advances in the branches of knowledge covered by the separate panels.

The first panel is concerned with fundamentals, standards and laboratory measurements, and Mr. Webb pays his tribute to the M.K.S. system while skilfully avoiding the more controversial aspects of the subject. The accuracy of definition of the fundamental units of mass, length and time has now been brought to about one part in 10^9 for mass, one part in 10^8 for length and one part in 10^{11} or better for time. Enthusiasts for new systems of units who favour a single arbitrary standard in place of the present three will have no difficulty in selecting time for this purpose.

The accuracy of establishment of the electrical units is perhaps somewhat disappointing, being about 1,000 times worse than the lowest accuracy of the fundamental units. It is therefore interesting that consideration should be given to the possibility of establishing a calculable standard of capacitance. To obtain an improvement in the establishment of electrical units by this method, it will be necessary to measure a capacitance of the order of 1 $\mu\mu$F. to an accuracy of 1 $\mu\mu\mu$F.—no mean feat of measurement.

The second panel is concerned with materials and components and there can be little doubt that Mr. Webb was justified in selecting, as the feature of greatest interest at the present time, the commercial production of germanium and silicon with impurity contents of less than one part in 10^8.

Measuring techniques, devices and instruments are covered by the third panel. This is a wide field where choice would be difficult. However, electrical joints occur in most electrical apparatus, sometimes in very great numbers.

The soldered joint made by a skilled operative has been long established and is still of great value, but occasionally a dry joint is obtained which may give trouble. Wrapped joints have now been developed, with a life expectancy of forty years, which can be made by unskilled operatives at great speed. The bound joint is an interesting variant in which wires of various diameters are bound together with binding wire of fixed diameter. This should simplify the design of wrapping tools.

The fourth panel is concerned with data processing, including analogue and digital computers. A vital component of the computer is the memory, which is often either a magnetic tape, a magnetic drum or a large number of magnetic elements such as ferrite toroids or straight magnetic wires.

The latest development involves the trapping of magnetic flux in a superconductor. This method holds out the hope of providing an access time about 1,000 times less than the fastest of the magnetic devices, but as the necessary equipment includes a helium liquefier the capital and operating costs of the memory may prove to be very high.

The fifth panel covers servo-mechanisms and control systems, a subject of some antiquity but one in which recent developments have occurred at a great rate.

The sensitivity and speed of response of modern servo-mechanisms are aptly illustrated by the possibility of controlling a magnetic field so that a piece of iron is held stationary between the upward pull of the field and the downward pull of gravity. Satisfactory damping has been achieved for this device.

A useful list of references is an unusual addition to a chairman's address, making it possible for the interested reader to go deeper into any subject of special interest to him.

DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH, NEW ZEALAND

ANNUAL REPORT

THE annual report* for the year ended March 31, 1958, of the Department of Scientific and Industrial Research, New Zealand, includes the usual statement by the Minister, the brief report of the Council and the longer report of the Secretary, together with reports from the branches and incorporated research associations. Some notes are included on grant-aided research at Canterbury Agricultural College, the Cawthron Institute, Massey Agricultural College and the University of Canterbury Industrial Development Department. Lists of publications are appended to the various departmental reports. Substantial effort was again devoted to the work of the International Geophysical Year, and a senior officer of the Department visited the New Zealand territories in the Pacific Islands to assess the agricultural problems to be solved if production is to meet the requirements of growing populations and satisfy the need for modern services and amenities.

Expenditure in 1957–58 was £1,535,000 gross, compared with £1,404,000 in 1956–57, the latter figure being 0·137 per cent of the national product. The Council believes that the future development of New Zealand depends very materially on scientific research and development, and urges that the percentage of national income should be increasing and not decreasing: during 1949–50 it was 0·173 per cent of the national product, and during 1951–52, 0·152 per cent. The professional staff of the Department at March 31, 1958, was 383, compared with 369 in the previous year, but was nineteen fewer than six years previously. In particular, the need to increase the work in nuclear science carried out by the Division of Nuclear Sciences and by the universities is emphasized, and the Council, after considering the position, envisages expenditure of some £500,000 to install and operate equipment to meet New Zealand's needs. Grants to research and allied institutions totalled £141,031, including £30,000 to universities and colleges of agriculture, and the Council is also concerned to extend the assistance at present given to industry.

The Secretary's report is mainly concerned with research completed during the year and includes a fairly full summary of the scientific activity in the Ross Dependency and in connexion with the International Geophysical Year. Scientific assistance given to the Police Department has included the use of paper chromatography for the separation and identification of barbiturates. The Philips electron microscope was installed at the Dominion Physical Laboratory in April 1958. The radiocarbon technique has been used to examine an ocean profile from the New Caledonian Trench, and preliminary investigations indicate that the method can also be used to study the circulation time and direction of underground water flow at Wairakei, while a theoretical study has been made of a possible way of extending the range of the carbon-14 dating equipment by isotopic enrichment using a thermal diffusion column. The sulphur isotopic variations in the sulphide and sulphate of geothermal bore waters have been used to estimate a temperature of 370 ± 70° C. for the hot chloride water underlying Wairakei.

---

* Report of the Department of Scientific and Industrial Research for the year ended 31 March, 1958. Pp. 90 (H.34.) (Wellington, Government Printer, 1958.)

Surveys over twelve years of areas susceptible to grass grub indicated that none of the land sown in introduced pastures and crops is absolutely free from grub attack, and as the texture of the soil improved, the land became more liable to attack. Grass grubs may be the main cause of weed encroachment on pasture lands, and the satisfactory control of grass grub in both North and South Islands has shown that pastures protected with DDT do not become infested with weeds. The decreased effectiveness in the past three years of the scale insect, *Eriococcus ovariensis*, as a controlling factor on manuka in the northern Hawke's Bay area appears to be due to the presence of a parasitic fungus capable of killing the scale insect responsible for manuka blight. An insect survey of agricultural crops in New Zealand was initiated, and a preliminary survey of grasslands in the North Island has already yielded much information on the distribution and relative abundance of more than 270 species of insects. Trials on rape selected for resistance to aphids proved as productive, or more productive, than the Broad Leaf Essex strain, and still grew well under aphis infestation sufficient to destroy the latter. Field trials by the Plant Diseases Division indicated that a recently introduced variety of swede, Doon Spartan, is comparable to the New Zealand bred variety, Calder, in resistance both to virus and to the cabbage aphid, but that the varieties resistant to cabbage aphid are not necessarily resistant to other aphids.

Research into the fundamental cause of bloat or tympanites of cattle indicates that the disorder is a very complex problem in plant–animal interrelations, and the various aspects of animal physiology, microbial metabolism and plant biochemistry involved are now being investigated. In grassland research an improved strain of *Lotus uliginosus* is under trial, but although more vigorous than those strains obtainable commercially, it is still slow to establish from seed, and work is in hand to improve the winter productivity. Work continued on the soil fertility cycle and the various aspects of fertility increase under pasture, fertilizer and the grazing animal and the decrease under different forage and food crops, and a study of seedling growth. Recent work by the Plant Diseases Division has shown that the death of pines in shelter belts is associated with the presence of *Phytophthora* species in the soil, and in connexion with this investigation the Auckland Industrial Development Laboratories have developed a method of measuring flow of sap by means of heat transport.

A survey of phosphorus in New Zealand soils has indicated the factors which determine the amount and nature of phosphorus in the soils, and, in turn, a better understanding of their requirements of phosphatic fertilizers. The survey has shown the dominating influence of soil processes in determining these requirements. The general soil survey of the South Island was used as a basis for constructing a map of the present utilization and possible development of land in the Otago district.

Discovery of a method of separating apple cells without altering their shape or size has considerably assisted the Fruit Research Division's measurement of cell size in Sturmer apples after different fertilizer treatments with a view of forecasting storage quality, and to meet the need of the stone-fruit industry for good descriptions the Division has started to sort out some sixty varieties of Japanese plums. 'Vapan' and allyl alcohol have given promising results for control of weeds in tobacco seedling beds, but the former must be used at least four weeks before the seed is sown, and excellent control of both types of stem rot was obtained by applying a drench of ferban or thiuram to the seedling beds. Investigations at the Cawthron Institute show that shade and high humidity are factors in the development of blotchy ripening, a physiological disease of tomatoes, and preliminary results at the Dominion Physical Laboratory indicate that the critical stage of fruit development is when the fruit is fully developed and just beginning to ripen. Observations have also been made on the rate at which rabbits recolonize an area, following complete destruction of the population.

ELECTRICAL DISCHARGES

THE Physical Society autumn conference on "Gas Discharges" was held at the University College of Swansea during September 17–20. The wide interest in this field of study was shown by the presence of some 200 delegates, including many from Australia, Germany, Norway and the United States. At the five sessions of the conference more than thirty papers from Government, industrial and university research laboratories were read. The present report is restricted to a brief description of a representative selection, grouped in accordance with subject-matter.

The conference was opened and the first session presided over by J. A. Ratcliffe (Cambridge), president of the Physical Society. The inaugural address was given by Prof. H. S. W. Massey (University College, London) and was devoted to a comprehensive review of recent experimental and theoretical advances in the study of atomic collisional phenomena, particular attention being paid to cross-sections for collisions of electrons with atomic hydrogen, on which a reliable body of theoretical knowledge now exists. The experimental method being used at University College, London, in which a modulated beam of atomic hydrogen is crossed by an electron beam and the resultant ionization analysed by a mass spectrometer, was described, later, by Dr. R. L. F. Boyd and A. Boksenberg (University College, London).

Other topics discussed in the inaugural address included the experimental verification in the U.S.S.R. and in the United States of the existence of a negative metastable ion of helium, previously predicted on theoretical grounds by two Norwegian investigators, and other results of recent work on negative ions. Of particular interest were the facts that the electron affinity of O^- has now been established as 1·45 eV., and that the cross-section for the production of I_2^- by slow electrons has been found experimentally to be surprisingly large ($\sim 3 \times 10^{-15}$ cm.^{2} for low-energy electrons).

Fundamental Processes

In an invited paper on "Investigation of the Secondary Processes in the Townsend and Streamer Regime", Prof. H. Raether (Hamburg) described oscillographic studies on the temporal growth of ionization in Townsend avalanches, and showed that values of the primary ionization coefficient α and the electron and ion mobilities may be obtained in this way. He also discussed studies under conditions in which the secondary ionization coefficient was so low (for example, in methane) that the primary amplification $e^{\alpha d}$ could attain very large values of the order of 10^8, and appeared to promote rapid breakdown originating from a single avalanche.

Prof. F. Llewellyn Jones welcomed the conference on behalf of the Department of Physics, University College, Swansea, and gave a short introductory account of recent work by the Swansea group. He stressed that with the mathematical treatment of ionized gases available to-day, only precision measurements can lead to the required data about fundamental ionization processes. Such significant measurements of, for example, ionization coefficients or of rapid current-growth can be made only when the state of purity of the gas and electrode surface is controlled; when the precise state of a cathode surface is unknown (because of the presence, say, of a thin film) the surface may still be specified by measuring its effective work function. Some recent results obtained with parameters thus controlled were described in the following papers.

From measurements of the temporal growth of ionization, Dr. E. Jones (Swansea) showed that with field stabilization and controlled conditions of electrode surface and purity of gas, 'scatter' of measurements was eliminated to give consistent values of formative time-lags, from which the individual secondary ionization coefficients (γ and δ/α) in hydrogen at pressures less than 10 cm. mercury were accurately deduced. The dependence of these coefficients on the work function of the cathode surface was also determined. Dr. J. Dutton (Swansea) reported recent precision measurements in hydrogen at high pressure of the secondary ionization coefficient, showing that this coefficient is a function of the gas pressure. It follows that the fundamental secondary process (ω/α) consists mainly of the cathode photo-emission produced by molecules excited in the avalanche, but that some excited molecules are destroyed by collisions of the second kind before they are able to radiate. Theoretical calculations of ω/α using known data for atomic cross-sections agree with the values measured.

Another paper dealing with measured work functions was read by Dr. E. Davies (North Staffordshire), who described the influence of work function in the range 2·0–4·5 eV. on the sparking potential in hydrogen at low pressures.

Measurements of pre-breakdown ionization currents in a range of pressures from 60 mm. mercury up to atmospheric pressure, which indicate the presence of considerable attachment ($\eta/p \sim 5 \times 10^{-3}$) for values of E/p from 25 to 45 V./cm. mm. mercury, were described by A. N. Prasad (University of Liverpool). Other recent work at Liverpool was described by M. C. Sexton, who discussed micro-wave studies on recombination and attachment in the afterglow of rare gases and oxygen, and by Prof. J. D. Craggs, who discussed the effect of electrons on the broadening of the Balmer lines. From measurements of the intensity of the Balmer continuum and its variation with time, values of the electron density and temperature were obtained, and using known values of the radiative recombination coefficients, the broadening effect of electrons was calculated.

Arc Discharges

An invited paper by Prof. J. M. Somerville (New England, Australia) described the study of anode marks made by an arc channel during the early stages of growth, from 20 mμsec. to 200 μsec. For pulses less than about 10 μsec. multiple spots were formed inside a circular area, the size of which increased for pulses up to 100 mμsec.; for longer pulses this area remained constant but the individual spots themselves grew bigger and finally coalesced. By considering the energy balance in the bright glow adjacent to cathode spots, M. A. Cayless (British Thomson-Houston, Rugby) deduced the factors governing the shape and size of the glow and the electron and ion currents at the cathode surface. Measurements, by Dr. H. Edels (Liverpool), of the gas temperature using shock-wave measuring techniques at varying times after the interruption of a low-current arc indicated thermal time-constants of about 500 msec. Dr. A. E. Guile and P. E. Secker (Queen Mary College, London) showed that the forward continuous motion of an arc cathode spot in a transverse magnetic field in air at atmospheric pressures is controlled by cathode surface conditions, velocity of motion being independent of the arc current between 40 and 700 amp. Using colour slides, L. A. King (Electrical Research Association, Leatherhead) discussed the jets observed in the high-current electric arc on the basis of a theory of dissociation and ionization and showed that these jets account for the metal transported in the welding arc.

Transient Discharges

An interesting group of papers was concerned with the operation of Sceptre III in the laboratories of Associated Electrical Industries at Aldermaston. Dr. N. L. Allen and Dr. R. M. Payne first surveyed the experimental techniques employed and discussed the correlation of results obtained from oscillographic studies, rotating-mirror photographs, magnetic search coil and spectroscopic investigations; these investigations indicated that the discharge could be stabilized to a certain extent. J. A. Wesson and B. S. Liley then discussed the determination of the inductance of the discharge and outlined a method by which the distribution of current in, and the motion of, the discharge and the extent to which the plasma traps the magnetic field within itself could be obtained from these measurements. Finally, Dr. H. T. Miles described an investigation of the mechanism of initiation of parasitic arcs inside the torus and methods used in controlling them.

Another paper in a closely related field was given by Dr. W. G. Townsend (Swansea), who discussed the liberation of electrons from cold cathodes in gases under electric fields $\sim 10^5$ V./cm. The mechanism involved emission due to the enhanced field produced by positive ions on a thin cathode film; measurements of electron liberation at 300° K. and 600° K. showed that the dependence on temperature was too small to be accounted for by local thermionic emission.

Recent work at the Atomic Weapons Research Establishment, Aldermaston, on shock waves from electrodeless discharges was described by G. B. F. Niblett. Interesting streak photographs of the luminosity produced by strong shock waves obtained in argon, helium and deuterium at low pressures by discharging energy (about 1,000 joules) through a single-turn external coil were shown and analysed.

Spark, High-Frequency and Glow Discharges

In order to accommodate the large number of papers submitted, the final session was divided into two sections, running concurrently. One of these, which was devoted to spark, high-frequency and glow discharges, contained two papers by members of the group working under the direction of Prof. F. M. Bruce (Royal College of Science and Technology, Glasgow) on long (~ 5-cm.) uniform field gaps in air at atmospheric pressure. D. T. A. Blair (in a paper with Prof. F. M. Bruce and J. E. Matthews) described simultaneous recordings of light and current pulses in such gaps at voltages just below the breakdown potential, and A. Aked (in a paper with Prof. F. M. Bruce and C. Gordon) described the effect of various parameters, showing that air circulation gives a more reproducible breakdown potential in an enclosed spark gap.

The problems encountered in the application of discharge techniques to industrial conditions were clearly, and often amusingly, illustrated in a paper dealing with electrostatic precipitators by J. S. T. Looms (Central Electricity Research Laboratories, Leatherhead). It was shown how the leakage of air into the flue gas in such precipitators could lead to spark-over.

Other papers in this session were concerned with measurements of breakdown at high frequencies, radio-frequency conductivity in afterglows, breakdown and maintaining potentials in helium – neon mixtures, and the advantages of deuterium over hydrogen as a filling for thyratrons.

Collision Processes and Energy Distributions

The other section of the last session was devoted to collision processes and energy distributions. Dr. J. Thompson (University College, London) concluded, from a study of the energy distribution and concentration of electrons and the temperature and concentration of positive and negative ions in oxygen discharges, that the destruction process for negative ions involves oxygen atoms. Probe measurements in striated positive columns were discussed in a paper by N. D. Twiddy, of University College, London (read by Dr. R. L. F. Boyd), and the existence of two well-separated groups of electrons demonstrated. Theoretical computations of α for argon, helium and neon using an energy distribution function for electrons derived directly from the collision cross-section were discussed in a paper by Dr. A. E. D. Heylen and Dr. T. J. Lewis (Queen Mary College, London). The phenomena attributable to the excitation of hydrogen by electron swarms were shown by Dr. R. W. Lunt (University College, London) to be explicable in terms of the experimental data for mono-energetic beams and the recent predictions of wave-mechanical theory. L. R. Griffin (Swansea) gave results of relative excitation cross-sections in helium computed from the intensities of lines in the spectra from high-frequency glow discharges. A paper by K. Persson (General Electric Research Laboratories, Schenectady), who was unable to be present, was read by Prof. F. Llewellyn Jones. The paper assessed the microwave technique and reported recent measurements on high-density plasmas, showing that the method can be greatly extended by applying solenoidal probing fields on plasmas with rotational symmetry.

During the conference the delegates were welcomed on behalf of the University College of Swansea by the vice-principal at a reception given by the College. Another much-appreciated feature of the proceedings was an afternoon break halfway through the conference, when delegates were enabled to see something of either the industrial life of South Wales at the Abbey Works of the Steel Company of Wales, or the scenic beauty of the Gower Peninsula.

J. Dutton
E. Jones

THE GENUS *DAPHNIA*

Daphnia is a genus of freshwater Crustacea the systematic study of which presents many difficulties, although the number of species in the world is not particularly large. The greatest difficulty arises from the fact that many of the species are very variable in conspicuous characters, such as the shape of the head. All the specimens of a species collected at any one time and place are usually very similar to one another, but specimens collected in different bodies of water often show great differences and also may undergo a cyclical series of changes with the seasons of the year. The seasonal rhythm, known as cyclomorphosis, is followed only approximately in the laboratory, and Dr. J. L. Brooks's first study of *Daphnia* was an investigation at Yale of environmental factors concerned, in which his discovery of the importance of the turbulence of the water was new and of great interest. The unsatisfactory state of the systematics of *Daphnia* has hindered his further studies on the evolution of the genus, and his recent memoir* on the systematics of North American *Daphnia* is a result of his very successful attempt to remedy this for that part of the world which concerns him, and since many of the species are also found in Europe and elsewhere, his results are of world-wide interest.

The early workers erected a great many names before it was realized how variable a species of this genus could be, but for the past fifty years or more there has been a great tendency to lump these together, many of the old names being kept for the numerous 'varieties'. Dr. Brooks gives strong support to those who have suggested that the lumping has been excessive, especially with a long series of forms which were called *pulex* if a comb was present on the claw of the tail, or *longispina* if the comb was absent. In Europe, under this scheme, the planktonic *Daphnia* of lakes are all varieties of *longispina*, exhibiting great diversity of form and often with marked cyclomorphosis, and *pulex* is confined to small bodies of water; in North America, on the other hand, it is *pulex* forms that inhabit the Great Lakes and exhibit a great diversity of form. Dr. Brooks finds, however, that the true *Daphnia pulex* occurs in North America, but it is found in ponds as it is in Europe, and he assigns other names to most of the species in lakes. He also finds, rather surprisingly, that *Daphnia obtusa* and the true *D. longispina* do not occur in North America, though *D. rosea* does. The latter was thought to be merely a variety of *longispina*, but good evidence for treating it as a separate species is produced, and the applicability of the name for the American specimens is shown by a reproduction of some pencil drawings made of Sars's type specimens by Richard before 1896. It is very fortunate that specimens of Sars's type material of this species now in the British Museum, and which Dr. Brooks had not seen, agree fully with his description. The identification as *D. rosea* of specimens of *longispina* from England in his collections, and also his opinion that *D. hyalina* and *D. galatea* (both also *longispina*) are distinct species, will, if substantiated, lead to changes in the names of British and other European species of *Daphnia*.

---

* Memoirs of the Connecticut Academy of Arts and Sciences, Vol. 13 (November 1957): The Systematics of North American Daphnia. by John Langdon Brooks. Pp. 180 (61 plates). (New Haven, Conn.: Connecticut Academy of Arts and Sciences, 1957. Obtainable also from Yale University Press.) 8 dollars.

In addition to extensive collections from most parts of North America, Dr. Brooks has made good use of the specimens, pencil drawings and other materials relating to the pioneer American workers, Forbes and Herrick, and also to the European authorities, Richard and Sars. This material has enabled him to find the correct names for the fifteen species which concern him from among names already published, in spite of the inadequacy by modern standards of the older original descriptions. To have found an appropriate name in each case, and to have been able to give his reasons clearly and convincingly, is a great tribute to his patience and skill. A lesser man would have invented a series of new names.

The bulk of the work is occupied by careful and very full descriptions of the fifteen species, with good line drawings and information on the geographical distribution and ecology. There is also a key to the species with the diagnostic characters figured at the side of the page, and an ingenious method of linking the drawings with the key. A separate part of the work is devoted to a discussion of ten separate regions of North America which the author has been able to distinguish on the basis of the distributions of the species, complex though these are.

Of particular interest in Britain is Dr. Brooks's discovery that *D. ambigua* is a widely spread North American species, for until now this species had been known only in England. It was first found in a pond in the Royal Botanic Gardens at Kew, and described by Scourfield in 1946, who suggested at the time that it had been introduced from abroad with aquatic plants.

This memoir whets the appetite for further publications in which an elaboration is promised of theoretical considerations, including the reasons for the author's belief in the adaptive significance of the extensive cyclomorphic variation in the genus *Daphnia*, which he suggests is the most interesting of the fruits of his study of their systematics.

J. P. Harding

A CLIMATOLOGICAL WIND TUNNEL

By Dr. P. E. WEATHERLEY and H. D. BARRS
University of Nottingham

In our studies of the water economy of plants it has proved necessary to subject as many as thirty large potted plants to known atmospheric conditions. For this purpose a wind-tunnel has been constructed at Nottingham which provides an air-stream of controlled speed, temperature and humidity. The control of these major atmospheric factors has been so successful that the details of the equipment may well be of interest in wider fields of research than those for which it was designed.

Our aim has been to control temperature, humidity and wind speed independently, thus making it possible to realize any one of a wide range of atmospheric conditions. Furthermore, it was not only necessary to hold any reasonable combination of temperature and humidity constant, but also to be able to change from one set of conditions to another fairly rapidly and even, if possible, to change conditions continuously and smoothly in a known way; in other words, to set a programme of climatic change. The equipment to be described fulfils these aims in large measure. The wind-speed can be varied between 2 and 16 ft./sec., the temperature between 10° and 40° C., and the relative humidity between 40 and 100 per cent at temperatures around 25° C., while at 35° C. a relative humidity as low as 25 per cent can be achieved.

In the first instance, no control of light has been attempted, natural light being used by constructing the working section of the tunnel of glass and erecting the tunnel in a glasshouse. Fig. 1 represents sections of the equipment seen from the side and end. The tunnel is of a closed-circuit type, and has a working compartment 12 ft. long, 3 ft. wide and 2½ ft. high, below which is a trough 14 in. deep for the pots. Thus, the pots are kept out of the main air-stream. This compartment consists of a wooden frame bearing glass panels, those forming the sides being fitted in felt-lined grooves to slide vertically and give access to the tunnel. The end sections and return duct underneath the working compartment are lined with tempered hardboard and have cavity walls for heat insulation.

The aerofoil fan *F* (Fig. 1) is belt-driven by an externally placed 4 h.p. d.c. motor connected to a Ward Leonard set giving speed regulation by voltage control. The air stream is deflected through two right angles by the guide veins *G*, through section *C* containing the sensitive elements of the control system, to the working compartment via the honeycomb *H*. This arrangement gives an even distribution of air-flow in the working compartment, no more than 5 per cent variation in wind-speed occurring across the tunnel. No guide veins are used at the

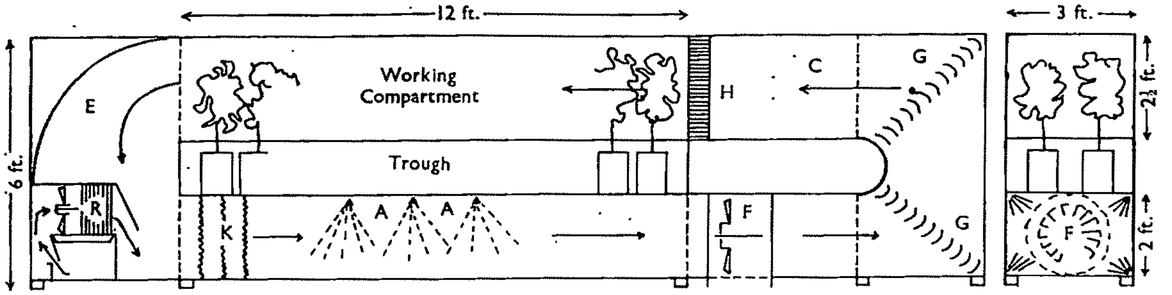

Fig. 1. Elevation diagrams of the tunnel viewed from the side and end

end *E*, since here turbulence is of little significance. The refrigerator *R* used both for cooling and drying the air is enclosed in a cabinet through which no air passes unless the refrigerator fan is in operation, when a part of the air-stream is drawn over the cooling coils. These coils are kept at a little above freezing point, and moisture condensing on them is collected on a tray beneath and drained to the exterior. The refrigerator compressor is situated outside the glasshouse. The heating elements *K* consist of bare coils strung across a frame and are arranged in three banks. One bank approximately balances the cooling effect of the refrigerator and is switched on automatically when the refrigerator is being used for dehumidifying the air-stream. A second bank is used for temperature control, and a third is manually operated to provide 'background' heating when the tunnel is operating at temperatures appreciably above ambient.

After passing over the heating elements the air-stream may be humidified by the atomizers *A*. These are operated from a compressed-air line and switched on and off by a magnetic valve.

Wind speed is set by adjusting the voltage of the d.c. supply to the fan motor, the voltmeter readings being calibrated in terms of wind-speed measured on an anemometer in the tunnel. Once set, the wind speed shows no detectable variation. The temperature and humidity control is of a simple 'on–off' pattern. The sensitive elements are resistance thermometers of platinum wire on mica formers unencased so that they are of low heat capacity and respond very rapidly to change of temperature. Each element forms part of a Wheatstone bridge circuit in which any unbalance due to a temperature-induced change in resistance of the element deflects a galvanometer. The position of the galvanometer needle whether at zero or to the left or right is automatically 'tested' every 10 sec. and according to its position the appropriate contactors are operated via mercury switches. Three resistance thermometers are used: one for temperature control and the remaining pair for humidity control on the principle of wet-bulb depression, one of the pair being draped in wet muslin, and the control operating on the difference in temperature between the wet and dry elements. The wet element is fitted with a small fan to ensure its adequate ventilation at low wind speeds. Each of the two bridge circuits with its galvanometer, synchronous motor, etc., is installed in a control box provided with a temperature scale and setting lever. In addition, each box can be fitted with a cam (of any desired shape), which alters the setting lever as it rotates and provides, instead of steady atmospheric conditions, a continuous change of temperature or humidity or both. This equipment is made up of standard commercial units and together with the specially designed resistance thermometers was supplied by the Foster Instrument Co., of Letchworth, Herts.

Operation of the control system is as follows. If the temperature in the tunnel falls below the set temperature, heating elements *K* are switched on (these can be varied between $\frac{1}{2}$ and 3 kW. and are set manually according to requirements). If the temperature rises above the setting, the refrigerator fan and compressor are switched on. Between these two there is a 'mid off' position having a range of 0·1° C., within which neither the refrigerator nor heaters operates. Similarly for humidity control, if the difference in temperature between the wet and dry elements is greater than the set value the atomizers are switched on. If the difference is less, the refrigerator fan, compressor and balancing heater are switched on. Here again there is a 'mid off' interval of 0·1° C. When cool, dry conditions are required, both the temperature and humidity controllers switch on the refrigerator, but in this event the balancing heater fails to operate and both a cooling and dehumidifying effect of the refrigerator is obtained. When cool, wet conditions are required, both the refrigerator and atomizers will operate, and here the humidifying effect of the latter must be sufficient to over-ride the dehumidifying effect of the former. This is merely a matter of having sufficient atomizers.

As yet the control of the tunnel is not entirely automatic. For precise control it is necessary to keep the 'on–off' heaters as small as possible, using a continuous background heater which would itself maintain the temperature at a little below the desired level. The power of this background heater depends on the difference between the desired level and that in the surrounding greenhouse. In the summer time the temperature of the greenhouse varied widely during the daytime, and this necessitated periodical manual adjustment of the background heaters. In fact, it would not be difficult to control these automatically in relation to the ambient temperature.

Ordinary meteorological thermographs and hygrographs have been used to record conditions in the working compartment. These are not necessarily reliable in recording the absolute levels of temperature and humidity under the conditions of violent change sometimes imposed upon them. But they are very sensitive to variations in conditions and respond rapidly; thus they are useful for testing the degree of control attainable. Absolute levels of temperature and relative humidity were checked using wet and dry bulb mercury thermometers. The instruments were shaded from direct sunlight.

The precision of control depends on the combination of temperature and humidity chosen and, of course, on the variation of temperature inside the glasshouse. A given temperature is usually maintained indefinitely within ± $\frac{1}{2}$° C. or better, and the relative humidity within ± 1 per cent or better. Examples of the performance of the control system are shown in Figs. 2 and 3. Stepwise changes in humidity at a constant temperature are shown in the upper part of Fig. 2. These were simply obtained by altering the humidity control setting from time to time. It will be noted that the change is effected rapidly; indeed, the humidity probably changed very quickly, the curves shown in the records representing the maximum speed of response of the hygrograph. The maintenance of constant humidity at various temperatures (Fig. 2, lower part) necessitated the adjustment of both the temperature and humidity controls at each step, the difference between the wet and dry bulb temperatures to give the same relative humidity at each temperature being obtained from tables. Deviations in relative humidity as much as ± 2 per cent occur during the change of temperature, but at each steady temperature the deviations are seldom more than ± 1 per cent.

As mentioned above, the control units could be fitted with programme cams giving continuous smooth adjustment of temperature and humidity. For a programme of changing humidity at constant temperature a cam is fitted to the humidity controller only. The result is shown in Fig. 3 (upper part). Varying temperature at constant humidity requires cams fitted to both temperature and humidity controllers; a typical result is shown in Fig. 3 (lower part). The cams in these two examples were eccentric circles giving sine curves of temperature or humidity, but asymmetrical cams or cams with fairly steep steps can be cut to give a wide variety of programmes. Also the speed of rotation of the cams can be varied within wide limits.

It should be emphasized that these results were obtained in a glasshouse often with intermittent sunlight and widely varying temperature. Fluorescent lighting is ultimately to be fitted around the outside of the working compartment and with this some control of the remaining major climatic factor should be achieved.

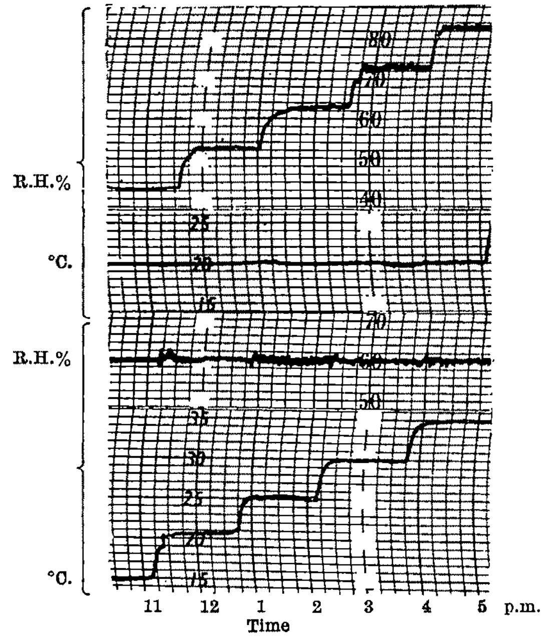

Fig. 2. Thermograph and hygrograph records taken in the working compartment. Upper part, various levels of humidity at constant temperature; lower part, various levels of temperature at constant humidity

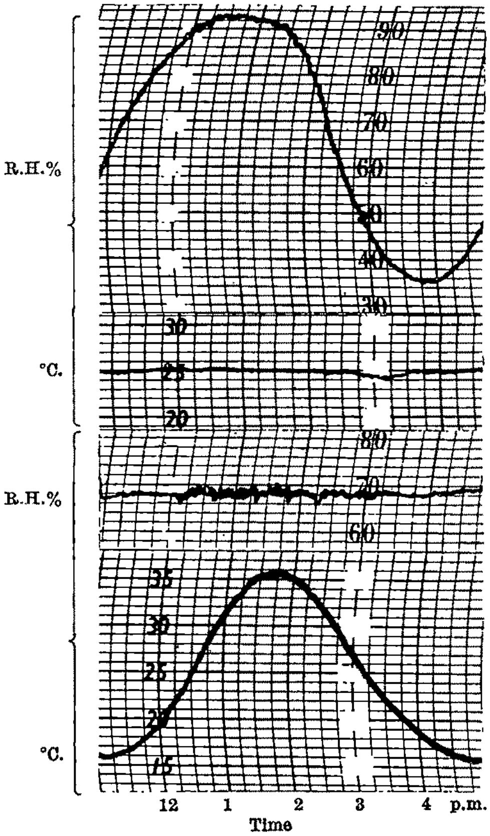

Fig. 3. Upper part, a programme of changing humidity at constant temperature; lower part, a programme of changing temperature at constant humidity

The success of this equipment can be attributed to three factors: (*a*) very sensitive control elements with low heat capacity; (*b*) equipment arranged to give clear-cut 'on : off' with as little carry-over as possible; this meant heaters of low heat capacity, refrigerator with a by-pass air current which could be stopped instantaneously, as could the atomizers; (*c*) excellent mixing in sequence such as is only achieved in a circulatory system.

The working compartment represents a bench space of 36 sq. ft.—equivalent to that in a small room. It is suggested that the air conditioning of an enclosed bench with circulation in the form of a closed circuit air stream gives more precise control than that of a whole room with less good or irregular mixing. A more detailed description of this equipment will be published in due course elsewhere.

We wish to thank the Nuffield Foundation for a grant of £1,100 and the University of Nottingham for a grant of £475. These together provided a sum covering the total capital cost of the equipment and a small part of the labour costs. The glasshouse with its services and the major part of the labour costs were not covered by the grants. Thanks are also due to Prof. C. G. C. Chesters for his generous provision of departmental facilities, to Mr. J. H. Broadbent for his skill and patience in constructing the tunnel, and to many colleagues for their advice.

SERUM ANTIBODY AND γ-GLOBULIN IN BABY RABBITS AFTER TRANSFER OF RIBONUCLEOPROTEIN FROM ADULT RABBITS

By Dr. MIROSLAVA HRUBEŠOVA*, Dr. BRIGITTE A. ASKONAS and Dr. J. H. HUMPHREY

National Institute for Medical Research, London, N.W.7

BABY rabbits in the first days of their life do not appear to give an antibody response to various substances, such as *Salmonella* antigens, *Brucella* antigens and bovine gamma-globulin, which are potent antigens in adult animals. The earliest age at which an antibody response can be elicited is usually about 20 days[1], though with large amounts of *Salmonella* antigen there may be some response in 10-day-old rabbits. This failure to form antibodies appears to be correlated with the fact that young animals do not form γ-globulin in appreciable quantities[2,3].

Recent work by Šterzl and Hrubešova[4] has shown that detectable antibodies to *Salmonella paratyphi B* appeared in the blood 3–5 days after intraperitoneal injection into 5-day-old rabbits of a ribonucleoprotein preparation from the spleens of normal adult rabbits, which had themselves received a dose (5×10^8 organisms) of heat-killed *Salmonella* two days previously, but the serum of which did not at that time contain detectable agglutinins. The injected ribonucleoprotein did not possess demonstrable antibodies as tested by the agglutination method.

It was of interest to know whether the antibodies in the baby rabbits receiving ribonucleoprotein were formed *de novo* in animals too young to react to antigens or arose from some transferred precursor. We attempted to determine this by injecting amino-acids labelled with carbon-14 into the babies and isolating the agglutinins. Newly formed antibody would be expected to be radioactive, whereas preformed antibody from the donor would remain unlabelled.

Isolation of Agglutinates following Injection of Ribonucleoprotein and Amino-acids labelled with Carbon-14 into Baby Rabbits

A suspension containing 5×10^8 heat-killed organisms of *Salmonella typhimurium* Glasgow (which has the same *O* antigen as *S. paratyphi B*) was injected, intravenously, into normal adult rabbits; donor rabbits were selected with serum agglutinin titres to *S. typhimurium* not exceeding 1 : 2. Two days later ribonucleoprotein was prepared from a saline extract of spleen by precipitation with ethanol[4] and injected, intraperitoneally, into half of a litter of 5-day-old baby rabbits, the litter mates being used as controls. In different experiments the babies received 400–900 μgm. of ribonucleoprotein containing less than 15–30 per cent of ribonucleic acid (based on estimates of total nitrogen and phosphorus). On the seventh and eighth postnatal day the injected and control babies each received, intraperitoneally, equal doses (35–50 μc. ≏ 1 mgm.) of amino-acids labelled with carbon-14 prepared by acid hydrolysis of biosynthetically labelled *Chlorella* protein (Radiochemical Centre, Amersham) and they were killed on the ninth postnatal day. These times were chosen in the light of the experiments of Šterzl and Hrubešova[4] showing that antibody titres reached a maximum 4–5 days after injection of ribonucleoprotein.

The sera from each group of baby rabbits were pooled and fat particles were removed by centrifuging for 60–90 min. at 18,000 *g*. The agglutinin titre was determined using 1 ml. of serum. The remaining serum (4–5 ml.) from both groups of rabbits was treated identically to determine the radioactivity of the specific agglutinins, and non-specific serum proteins absorbed on to the bacteria. Excess *S. typhimurium* (0·7–1 × 10^9 organisms/ml. serum) were added to the serum, which had been diluted with an equal volume of saline containing 0·2 per cent of neutral ethylene diamine tetraacetate and 30 mgm. mixed amino-acids (added to minimize adsorption of amino-acids labelled with carbon-14 and complement on the organisms). After 2 hr. at 37° C. and 2–3 days at + 4° C., the organisms were collected by centrifugation, washed twice with normal rabbit serum (containing no detectable agglutinins), once with saline and once with water. The organisms were suspended in 5 *N* ammonium hydroxide, dried on 2 cm.^{2} polyethylene disks and their radioactivity determined at infinite thinness with a thin window counter. To obtain the specific radioactivity of the agglutinins, the amount of protein absorbed on the bacteria was determined by the method of Lowry *et al.*[5] after extracting the organisms with 0·1 *N* sodium hydroxide. The extractable protein content of the organisms was determined by washing and extracting a saline suspension in the same way, and was deducted so as to obtain the amount of protein absorbed on the bacteria from the sera.

The results of such experiments are shown in Table 1. Although in two of the three experiments *O* agglutinins appeared in higher titres in serum of babies treated with ribonucleoprotein from injected donors than in serum of controls, it is evident that considerable non-specific adsorption of serum proteins on the bacteria occurred in all cases and there were no striking differences in the specific radioactivity of the absorbed proteins in the different groups of rabbits. By comparing agglutinin titres and precipitating antibodies of a serum from a rabbit hyperimmunized against purified soluble *O* antigen, we have estimated that an agglutinin titre of 1/16, under our experimental conditions, corresponds to less than 0·4 μgm. antibody per ml. Thus, the amounts of specific antibody to be sought in the babies' serum samples were not more than 2 μgm. To measure the radioactivity of such small quantities would only be possible if non-specific uptake of other proteins could have been completely eliminated. Therefore, no conclusions can be drawn as to whether or not the agglutinins were formed *de novo*

---

Table 1

Exp. No.†	Material injected	Agglutinin titre of pooled sera	Weight of serum protein eluted from bacteria (μgm./ml. serum)	Sp. activity of serum protein eluted from bacteria (cts./min./100 μgm.)
694	RNP from injected donor	1/16 +	20	94
	—	1/4 ±	13	76
740	RNP from injected donor	1/2 +	65	27
	—	1/2 ±	81	30
800	RNP from injected donor	1/16 +	36	113
	—	1/4 ±	17	150
724	RNP from normal donor and 0·5 μgm. *O* antigen	1/2 −	152*	15·7
	0·5 μgm. *O* antigen	1/2 −	124*	28·3
	—	1/2	122*	23·2

* *S. typhimurium* organisms added to undiluted serum in the absence of versene.

† Litter mates were used for each experiment with 2–3 babies per group.

RNP = ribonucleoprotein.

in the baby rabbits which received ribonucleoprotein.

Test for Preformed Antibody in Ribonucleoprotein

The possibility that antibodies were passively transferred with the ribonucleoprotein preparation was considered by Šterzl and Hrubešova[4], but they could not detect agglutinins in the material which they used for transfer. We found that the sera of normal rabbits from all the stocks available to us—even though classed as negative by direct agglutination tests—contained detectable antibodies (1/8–1/16) against the *O* antigen of *Salmonella typhimurium*, when tested by the more sensitive hæmagglutination technique[6], using red cells sensitized with a purified *O* antigen kindly provided by Dr. D. A. L. Davies. This suggested that the rabbits might have been subject to weak stimulation with some related antigen (for example, from the intestine or from inhaled dust); this suggestion was strengthened by observing that injection of 0·02 μgm. of the *O* antigen into our normal rabbits gave rise to high titres of agglutinins within 4 days—characteristic of a secondary, rather than of a primary, response. If this is so, it might be expected that the spleen taken from donor rabbits two days after injection of *S. typhimurium* would already be making some antibody, and that the ribonucleoprotein fraction (which was prepared in in such a way as to contain γ-globulin) might contain sufficient antibody to give rise to agglutinins in the recipient babies.

We therefore re-investigated this question, and treated the ribonucleoprotein with ribonuclease, trypsin and carbonate buffer *p*H 9·5, in an attempt to release antibody complexed with nucleic acid or other proteins. We were, however, unable to detect preformed agglutinins in the ribonucleoprotein by the hæmagglutination technique. With the possibility in mind that living tissue might split off antibody, ribonucleoprotein was added to the perfusing fluid in the isolated perfused lung system described by Askonas and Humphrey[7], and the fluid was examined for the presence of antibody after various time intervals. None was detectable after up to 6 hr. of perfusion. Furthermore, we found that ribonucleoprotein had no inhibitory effect on the agglutination reaction, even when tested with minute quantities of antibody. There is, therefore, no evidence that agglutinins appearing in the babies after three days were due to passive transfer of preformed antibody. If such transfer is the explanation, the antibodies must be present in some masked form. There is also the possibility that antigen–antibody complexes are present, since Šterzl and Hrubešova[4] found indirect evidence for occasional transfer of traces of antigen.

Incorporation of Amino-acids labelled with Carbon-14 into Plasma Proteins in Baby Rabbits

These experiments provided an opportunity for observing the degree of incorporation of amino-acids labelled with carbon-14 into plasma proteins in 7–9-day-old rabbits. After absorption of the sera with *S. typhimurium* the specific radioactivity of the remaining proteins was measured as follows: albumin, α-globulin and β-globulin were isolated from 1 ml. of serum by electrophoresis on treated cellulose columns[8]. The fractions were dialysed under pressure, protein precipitated with trichloroacetic acid, and the radioactivities of the dried washed proteins determined at infinite thickness. There was insufficient γ-globulin in these sera to permit isolation by this method, and we therefore used the diethylaminoethyl cellulose ion-exchange column described by Peterson and Sober[9]. By using 0·015 *M* phosphate buffer, *p*H 6·0, γ-globulin could be isolated, contaminated only, in some sera, with hæmoglobin. The extent of such contamination was estimated colorimetrically and, when it was significant, hæmoglobin was prepared from pooled red cells of the rabbits in the same experimental group, and its specific activity measured, in order to permit correction of the γ-globulin radioactivity measurements.

The total protein content (by Kjeldahl nitrogen estimation) of 9-day-old rabbits' sera was about two-thirds that of adult serum. The percentage of the component serum proteins was similar in all groups of baby rabbits, as judged from the elution diagrams of the columns based on the ultra-violet absorption of the protein at 280 mμ. Sera from adult rabbits were treated similarly, for comparison, and average values are given in Table 2. The concentration of γ-globulin was about 1 mgm./ml. as confirmed by immunochemical estimations, using goat anti-rabbit serum rendered specific for rabbit γ-globulin by absorption with other rabbit serum fractions.

Table 2. PROTEIN COMPOSITION OF SERA OF 9-DAY-OLD AND ADULT RABBITS

	Per cent of total serum protein (based on measurement of protein absorption at 280 mμ)	
	9-day-old rabbit	adult rabbit
Albumin	66·5	59
α-Globulin fraction	19·5	5·5
β-Globulin fraction	10·5	18·5
γ-Globulin	3·5	17

All the serum proteins became labelled, and it is of some interest to compare the relative specific activities with those found in adult rabbits 48 hr. after injection of a similar mixture of amino-acids labelled with carbon-14. Our findings are shown in Table 3, in which it may be seen that, with the exception of γ-globulin, the relative incorporation of amino-acids labelled with carbon-14 into the various fractions was similar in both treated and control groups of babies, and not very different from the results in the adult rabbit.

Table 3. RELATIVE RADIOACTIVITIES OF SERUM PROTEINS 48 HR. AFTER ADMINISTRATION OF AMINO-ACIDS LABELLED WITH CARBON-14 (Values are means of several experiments and are expressed as percentages of the radioactivity of serum albumin)

Group	Albumin	α-Globulin	β-Globulin	γ-Globulin
Adult rabbits	100	170	155	70
Control 9-day-old rabbits (3 exps.)	100	135	123	14
Babies (9 days) injected at 5 days with ribonucleoprotein (3 exps.)	100	134	133	38

Since the extent to which a labelled amino-acid becomes incorporated into plasma proteins depends upon several factors (such as the rates of synthesis and degradation, pool size, and amino-acid composition of the protein), detailed interpretation of these results is not possible with the results available. Comparison of the two groups of babies is, however, valid. Incorporation of carbon-14 into γ-globulin (and hence the rate of synthesis) is strikingly low in both groups, especially when the very small size of the γ-globulin pool is considered. However, it was two to three times greater in the rabbits which received ribonucleoprotein than in the controls, whether or not there was a detectable rise in antibody titre. This indicates that γ-globulin synthesis, although still very small, was stimulated by the injections of ribonucleoprotein. By what mechanism this effect was produced we are unable to say. In all but one experiment, in which the spleen of one control baby was quite abnormally large, the spleens of animals in the ribonucleoprotein groups were 10–40 per cent heavier than those of control animals, after correcting for any differences in body-weight. The possibility that this was due to stimulation of plasma cell proliferation by the ribonucleoprotein was examined histologically, in sections of spleen stained with pyronin and methyl green. Plasma cells were, however, too few to be detected, in any of the babies' spleens—an observation which excludes such cells from being the main factor in splenic enlargement, though not necessarily in γ-globulin formation.

REACTION OF SOME SILICATES WITH CHELATING AGENTS

By DR. D. A. SUTTON, M. D. MIDDLETON and R. A. F. BODY

Pneumoconiosis Research Unit, Council for Scientific and Industrial Research,
South African Institute for Medical Research, Johannesburg

MINERAL silicates have been directly implicated as fibrogenetic agents in certain of the pneumoconioses (for example, asbestosis) and conceivably play a part in others. For example, Witwatersrand gold miners suffering from 'classical' silicosis have inhaled silicates in addition to quartz. If silicates and quartz dissolve *in vivo*, the silicate ions released may produce precipitated silicates by reaction with body metals. It was therefore decided to explore the reaction of some mineral and precipitated silicates with chelating agents. It was found that removal of metal from silicates resulted in breakdown of the silicate lattice and the release of silicate ion. Chelating agents may also be useful in that they offer possibilities for accomplishing ion exchange on the surface of the causative agents of the pneumoconioses; this is the subject of a forthcoming publication[1].

The silicates used were (*a*) olivine, crocidolite, antigorite, chrysotile, talc and orthoclase from South African mines; (*b*) those of Ca^{2+}, Mg^{2+}, Al^{3+}, Fe^{2+} and Cu^{2+} precipitated from aqueous solutions; (*c*) tricalcium silicate made at 1,500° C. Most experiments were done with ethylenediamine tetraacetic acid as chelating agent; but penicillamine and glycine were also tried.

100-mgm. samples of each mineral (1–100μ diameter particles unless otherwise stated) were agitated with 26·5 ml. aqueous 0·75 *M* ethylenediamine tetraacetic acid (trisodium salt), that is, enough to chelate several times the metal present. The reagent was buffered to *p*H 7·4 by adding 0·315 gm. H_3BO_3 and 0·05 gm. $Na_2B_4O_7.10H_2O$. Control experiments using the buffer solution only gave less than 10 per cent of the values obtained with ethylenediamine tetraacetic acid with most of the minerals and have not been deducted from the results presented except as indicated. In process 1, the reactions were not disturbed except for the removal of small volumes of supernatant for analysis. In process 2, the mixtures

* Boiling point of solution in Johannesburg.
† Reaction continues using process 2
‡ Reaction continues very slowly using process 2 ; the high control values (45–60 per cent) have been deducted.

were centrifuged hourly and the supernatants replaced by fresh reagent. The percentages dissolved were determined by silicate[2], iron[3] and magnesium[4] analyses as appropriate on the supernatants.

At 93° C., antigorite, chrysotile and olivine reacted fairly rapidly, orthoclase did not react, and crocidolite and talc reacted slowly. Antigorite and chrysotile continued to react until near completion using process 2 at 93° C. (Fig. 1), and the cessation of reaction noted in process 1 was due to the deposition of silicate on the particles. This was proved by taking antigorite which had ceased to react after seven hours, using process 1 at 93° C. and re-treating it with fresh reagent; the mineral then again began to dissolve, but the supernatant contained disproportionately more silicate than magnesium.

The 1-cm. chrysotile fibres reacted at about one-fifth of the rate of the powder, which was at least 200 times shorter. Antigorite and chrysotile particles of similar size reacted at almost identical rates (Fig. 1). In view of these facts and the published structures[5,6] of the two minerals, it appears that reaction with ethylenediamine tetraacetic acid probably occurs by abstraction of metal from the Mg—OH (outer convex) layer. In olivine, metal ions occur on outer surfaces, but in talc (which reacts very slowly) they do not. Crocidolite reacted slowly, although recent literature[7] groups it with amphiboles, that is, having metal ions on the outer surface. Orthoclase, in which aluminium replaces silicon in the lattice, does not react.

Neither glycine nor *d*-penicillamine, both of which are weak chelating agents, reacted with chrysotile at 93° C.

Precipitated silicates were prepared by adding sodium silicate solution with rapid stirring to metal salt solutions at 37° C. The *p*H's of the metal salt solutions had been adjusted so that the final *p*H after adding the alkaline (*p*H 11·5–12·0) silicate solution was as high as possible without causing precipitation of the metal hydroxide. The thoroughly washed precipitates were shaken for five minutes three times at 37° C. with 0·75 *M* ethylenediamine tetraacetic acid in 0·9 per cent saline (*p*H 7·4). The extents of reaction were determined by analysis of the supernatants, namely, for calcium (flame photometry on the oxalate), magnesium[4], aluminium[8], iron[3], and copper (as the ethylenediamine tetraacetic acid chelate colorimetrically at 725 mμ).

Table 2. REACTION OF PRECIPITATED SILICATES WITH ETHYLENEDIAMINE TETRAACETIC ACID

Metal	m.moles metal mixed with 1 m.mole silicate (as SiO_2)	Mixture volume (ml.)	m.moles metal per m.mole silicate (as SiO_2) in precipitate	Percentage reaction
Ca^{2+}	0·44	6·3	0·24*	
Ca^{2+}	1·02	2·7	0·46	100
Ca^{2+}	2·18	10·3	1·3*	
Ca^{2+}	15·00	163·0	2·1*	
Mg^{2+}	1·03	2·7	0·56	100
Al^{3+}	1·03	5·2	0·68	13
Fe^{3+}	0·98	7·7	0·26	100
Cu^{2+}	1·03	2·7	0·71	100

* Included to show that composition depends on ratio of metal/silicate used.

Only the precipitated aluminium silicate failed to dissolve completely under the conditions used. Aged copper silicate (five weeks) behaved in the same way as that freshly prepared.

Synthetic tricalcium silicate[9] (actually 70 per cent $3CaO.SiO_2.1\frac{1}{3}H_2O$ and 30 per cent $5CaO.2SiO_2.H_2O$ [10]) dissolved within five minutes at 25° C. in the ethylenediamine tetraacetic acid solution. This material thus reacted far more rapidly than olivine, a member of the same structural group.

It is apparent that ethylenediamine tetraacetic acid at body temperature reacts so slowly with the mineral silicate types studied that its therapeutic application in this respect, if any, will be restricted to a few special cases. Since magnesium is lower in the ethylenediamine tetraacetic acid – metal stability series than calcium, calcium ethylenediamine tetraacetic acid is, in any event, inapplicable to the *in vivo* removal of olivine, chrysotile or antigorite. Precipitated silicates of metals higher than calcium in the ethylenediamine tetraacetic acid series (if they exist *in vivo*) would probably be removable by calcium ethylenediamine tetraacetic acid.

We wish to record that we decided to carry out this work following the administration of calcium ethylenediamine tetraacetic acid to a miner which had been suggested by Dr. Harriet Hardy.

We thank Dr. I. Webster for discussion, Dr. H. F. W. Taylor for the tricalcium silicate and Mr. W. J. van Biljon for mineral silicates. Some of the preliminary experiments were carried out with Mr. L. W. Marasas.

PHYSICAL SCIENCES

Possibility of Ion Runaway in Zeta

Above a certain critical velocity the rate of loss of momentum of an ion in Coulomb collisions with other particles decreases with relative velocity. This leads to the possibility that ions in a plasma can be continuously accelerated by an electric field. Such ions are called 'runaway' ions.

George[1] has suggested that some of the observations on Zeta[2] can be explained in terms of runaway ions. By modifying an expression[3] applicable to runaway electrons and by ignoring ion – electron collisions, George obtains a condition for ion runaway based solely on ion – ion collisions. This procedure is not permissible. The velocity of those ions on the Maxwell tail of the ion distribution is much less than the mean thermal velocity of the electrons ($\overline{w}_e$) and so the frictional force on these ions due to the electrons increases with the ion velocity, and becomes very much larger than the ion – ion friction force. The class of electrons which can gain energy continuously consists, on the contrary, of the fastest particles in the plasma (apart from the runaways), so that their rate of loss of momentum decreases with increasing electron velocity.

The condition for an ion to 'runaway', in a fully ionized plasma, can be derived from the investigations of Chandrasekhar[4] by replacing his gravitational interactions by their electrical analogues. A singly charged test ion moving with velocity w_i through a Maxwellian distribution of electrons will experience a frictional retarding force given by[4,5]:

$$f = \frac{8\pi e^4 n_e \log\Lambda}{m_i} l_e^2 \left(1 + \frac{m_i}{m_e}\right) G(x) \tag{1}$$

where

$$\left.\begin{aligned} x &= l_e w_i,\ l_e^2 = m_e/2kT_e, \text{ that is, } l_e^2 w_i^2 = \frac{3}{2}\frac{w_i^2}{\overline{w}_e^2} \\ G(x) &= \frac{\Phi(x) - x\Phi(x)}{2x^2};\ \Phi(x) \doteq \frac{2}{\sqrt{\pi}}\int_0^x \exp(-y^2)\mathrm{d}y \end{aligned}\right\} \tag{2}$$

The subscript i refers to ions and e to electrons; m is particle mass; n, particle density; e, electronic charge; k, Boltzmann's constant; and Λ, the ratio of the Debye shielding distance to impact parameter for 90° deflexion[5].

If the velocity of the ion is less than the mean thermal velocity of the electrons then the frictional force increases with the relative velocity; if, on the other hand, the ion velocity is greater than the mean electron velocity the friction force decreases with increasing velocity.

First let the velocity of the test ion be appreciably greater than the mean thermal velocity of the electrons, in particular if:

$$w_i/\overline{w}_e > 1{\cdot}6 \tag{3}$$

then from (2), to within about 5 per cent:

$$G(l_e w_i) \simeq \frac{1}{2 l_e^2 w_i^2} \tag{4}$$

and (1) becomes:

$$f = \frac{4\pi e^4 n_e \log\Lambda}{m_e}\ \frac{1}{w_i^2} \tag{5}$$

that is, the friction force is proportional to $1/w_i^2$.

Thus, for sufficiently high initial velocity, the applied electric force will exceed the friction force and the test ion will runaway. In Zeta, however, the velocity of the ion is only greater than the mean thermal velocity of the electrons if the ion energy is greater than 200 keV. (assuming $T_e = 5 \times 10^5$, see ref. 6). The observed[7] ion energies are less than 20 keV.

Now let the ion velocity be less than the mean velocity of the electrons, say:

$$w_i/\overline{w}_e < 0{\cdot}5 \tag{6}$$

then from (2)

$$G(l_e w_i) \simeq 0{\cdot}376\, l_e w_i \tag{7}$$

and (1) becomes:

$$f = \frac{8\pi e^4 n_e \log\Lambda\ m_e^{1/2}}{(2kTe)^{3/2}} \cdot 0{\cdot}376\, w_i \tag{8}$$

that is, the friction force increases with increasing velocity and runaway is not possible. In fact, the ions reach a terminal velocity which is given by equating the applied electric force to the friction force; it is:

$$w_T = \left(\frac{ET_e^{3/2}}{n_e}\right)\frac{k^{3/2}}{\pi e^3 \log\Lambda\ m_e^{1/2}} \times 0{\cdot}94 \tag{9}$$

Since w_T has been calculated using a stationary Maxwellian velocity distribution for the electrons, it is relative to the drift velocity of the electrons. The electric field acting on the ions also acts on the electrons, and hence the terminal velocity w_T is physically the same as the drift velocity of the electrons, relative to the ions, which governs the resistivity of the plasma. The present calculation does not take into account the fact that the electron and ion distributions in an electric field are not Maxwellian and so cannot give an accurate value for the electron–ion drift velocity. A more accurate value is implicit in the distribution function obtained by Cohen *et al.*[8].

The above considerations show that runaway ions cannot occur in the conditions which apply on the average in Zeta. It is still, of course, possible that ion 'runaway' occurs in restricted regions of the discharge where conditions are abnormal. Examples of such regions are: regions where the electron velocity is limited by other means than collisions with the deuterons; regions of low electron temperature into which particles may be injected, from other parts of the plasma, with sufficient energy to satisfy (3); regions largely occupied by runaway electron streams, where ion – electron collisions are unimportant.

There is as yet insufficient evidence to show whether or not any such regions exist.

I am indebted to E. R. Harrison, R. S. Pease and W. B. Thompson for many discussions on this subject.

A Non-Thermal Direct-Current Plasma-heating Mechanism

THE power required to heat a plasma to thermonuclear temperature may be greatly reduced if one can apply the ion relaxation principle suggested by Schlüter[1] and also (in a different form) by Motz (unpublished work). In the Schlüter scheme, an oscillation in a magnetic field-strength at a frequency much lower than the frequency of electron collision heats the ions quickly, without appreciably heating the electrons. Since, in a plasma at equilibrium, the electrons are responsible for nearly all the loss of heat, this is a great advantage. In this communication it is shown that, under the influence of an axial unidirectional electric field (as in Zeta and Sceptre), the orbits of electrons in a plasma are distorted in such a way that they feed power to travelling compression waves in the plasma. It is conceivable that, by this means, and with a suitable choice of parameters, a substantial fraction of the total power available to a ring discharge might be converted to ion energy.

Let us suppose that the magnetic field, B, is:

$$B_z = B_0 [1 + \alpha^2(z - v_a t)^2] \tag{1a}$$

$$B_r = -\alpha^2 B_0 (z - v_a t) r \tag{1b}$$

with B_0 and α constants, z, r and t position and time co-ordinates, and v_a the velocity of the potential well. (In a gas discharge, v_a will be approximately the Alfvén velocity, $cB_0(\varepsilon_0/\rho)^{1/2}$; see also ref. 2.) An electron moving in this magnetic field can be characterized by its magnetic moment μ, where:

$$\mu = m v_\perp{}^2/2B \tag{2}$$

with $v_\perp$ being the component of the velocity normal to B. The parameter μ is very nearly a constant of the motion[2]. We consider motions in the vicinity of the $z - v_a t$, r origin. The restoring force on the electron is:

$$f = -\mu \nabla_{z'} B = -2\mu\alpha^2 B_0 z' \tag{3a}$$

where $z' = z - v_a t$. The electron thus has simple harmonic motion about $z' = 0$, at an angular frequency ω, where:

$$\omega = (2\mu\alpha^2 B_0/m)^{1/2} = \alpha v_\perp (z' = 0) \tag{3b}$$

In this motion, the magnitude, v', of the velocity of the electron, measured in the primed frame, is also nearly constant. If a small electric field, $-E_z$, is applied, so that $|eE_z/\alpha m v'^2| \ll 1$, the motion is still nearly harmonic, but the oscillation will now be centred about $z' \simeq eE_z/2\mu B_0\alpha^2 = z_0$.

For a simple example, suppose the electron orbits in a plane normal to the z-axis at z_0. The force eE_z on the electron is balanced by the magnetic force $ev_\perp B_r$, and in a time-interval Δt the work done on the magnetic field is $\Delta W_z = f_z \Delta z = ev_\perp B_r \Delta z = eE_z v_a \Delta t$. In this case, all the work done upon the electron by the E_z field is passed on to the B field.

In the above example, the radial component of the force did no work. This is also true for the case of an electron which oscillates in z', when we average over a complete cycle. Choosing an appropriate z-axis, we have $mv_\perp = B_z e r$, and:

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{mv_\perp}{eB_z}\right) = \frac{m}{e}\left[\frac{1}{B_z}\frac{\mathrm{d}v_\perp}{\mathrm{d}t} - \frac{v_\perp}{B^2{}_z}\frac{\mathrm{d}B_z}{\mathrm{d}t}\right] \tag{4}$$

while, using (2), we have:

$$mv_\perp \frac{\mathrm{d}v_\perp}{\mathrm{d}t} = \frac{\mu \mathrm{d}B_z}{\mathrm{d}t} \tag{5}$$

setting μ constant. Combining (2), (4) and (5), we get $\Delta W_r = \int f_r v_r \mathrm{d}t = \int ev_\perp B_z \frac{\mathrm{d}r}{\mathrm{d}t}\,\mathrm{d}t = \mu\Delta B$, which vanishes, when taken over a complete cycle.

For the work done against B_r in the vibratory case, we use (1*b*), (2), and the centrifugal force equation, getting $f_z = ev_\perp B_r = 2\alpha^2\mu B_0 z'$. Setting $z' = z_0 + z_m \sin\omega t$, and $v_z = v_a + \omega z_m \cos\omega t$, we have:

$$W_z = \int f_z v_z \mathrm{d}t = 2\alpha^2 B_0 \mu \int (z_0 + z_m \sin\omega t) \times (v_a + \omega z_m \cos\omega t)\mathrm{d}t \tag{6}$$

which, after integrating, and substituting for z_0, gives:

$$\Delta W_z = 2\alpha^2 B_0 \mu z_0 v_a \Delta t = eE_z v_a \Delta t \tag{7}$$

for the work done during a complete cycle.

If E_z is reversed, this effect gives a decrease in the energy of the magnetic perturbation.

It is tempting to generalize this result into the following rough rule: in a plasma, an electron that moves undisturbed through a complete vibratory cycle in its B potential well will divert all the energy it has gained from E_z in the interval to the magnetic field.

The fraction of the electrons in a discharge which will feed energy in this way to the compression waves in B will depend upon the electron temperature and the amplitude oscillations of intensity B. Under suitable conditions, the oscillations will be built up, and, if their frequency is appropriate, they will heat the plasma ions by the Schlüter mechanism. It is possible that such oscillations contribute to the remarkably fast ion heating in current experiments[3].

Difference between Cosmic-Ray Equator and the Geomagnetic Dip Equator

After several recent measurements on the latitude effects of cosmic-ray intensities[1-3] it has been suggested that the cosmic-ray equator coincides well with the geomagnetic dip equator rather than the geomagnetic dipole equator. Even if this is so, however, there is still a considerable discrepancy between the cosmic-ray and dip equators. One explanation of this discrepancy may be an inaccuracy of the position of the dip equator itself, because the dip equator is a curve obtained by interpolations among the observation points.

During the voyage of the *Soya* on the second Japanese Antarctic Research Expedition, measurements of geomagnetic total intensities were carried out crossing the geomagnetic equator in the South China Sea. The daily range of total intensity (F) was found for each day around the geomagnetic equator and compared with that at the magnetic observatory at Muntinlupa, in the Philippines. Although the ratio of the range on the ship to that of Muntinlupa varied considerably from day to day, a smoothed curve shows a remarkable feature of F against geomagnetic dip angle, as shown in Fig. 1. It is clear that the region of maximum range in F is about 4° south of the geomagnetic dip equator.

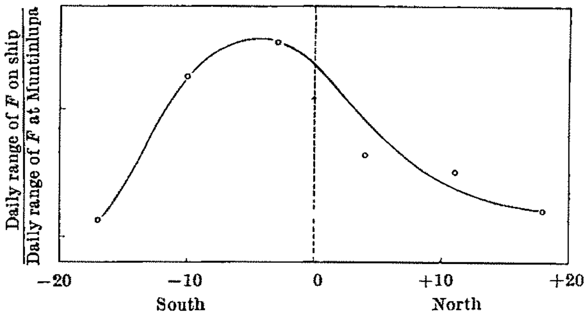

Fig. 1

On the other hand, cosmic-ray intensities measured on the same course during the first Japanese Antarctic Expedition show that the position of minimum cosmic-ray intensity was found at 6° north geographical latitude, which is situated at about 3° south of the geomagnetic dip equator[4]. Consequently, the cosmic-ray equator coincides with the geomagnetic dip equator deduced from the daily ranges of geomagnetic total intensities in the South China Sea, or along about 110° east geographical longitude.

These conclusions are valid on the assumption that the position of the geomagnetic dip equator is not necessarily accurately defined. Next, let us assume that the geomagnetic dip equator is accurate. In this case similar results are obtained around the geomagnetic dip equator in Africa[5], South America and India[6], except for a slight difference between the position of the maximum daily range in F and the geomagnetic dip equator. Since it has been suggested that an explanation can be found in the superposition of the effect of a narrow equatorial jet-current due to the Hall effect in the ionosphere[7], the area of maximum range in F is situated in the area of zero dip angle in the ionosphere. Therefore, it is suggested that the geomagnetic field is more effective in cosmic-ray intensities existing in the vicinity of 100 km. above sea-level than the geomagnetic surface anomalies, which decrease with height from the Earth's surface to the lower boundary of the ionosphere.

We would like to express appreciation to Prof. T. Nagata and Dr. Y. Miyazaki for their interest and encouragement during the expeditions.

Infra-red Dispersion Wave-lengths for Solid Lithium Fluoride containing Varying Proportions of Lithium Isotopes

In a programme utilizing isotopic mass as a probe for the solid state, the infra-red dispersion wave-lengths of ^{6}Li^{19}F and ^{7}Li^{19}F were recently obtained[1]. Since then, improved apparatus and techniques have allowed a somewhat better estimate of these wave-lengths. Moreover, the study has been extended to lithium fluoride containing varying proportions of the lithium isotopes. Lithium fluoride was prepared by the action of hydrofluoric acid on metallic lithium and its oxide, nitride, etc., resulting from exposure to the atmosphere. The enrichment of the lithium-6 sample was specified as 99·3 ± 0·2 per cent, and that of the lithium-7 as 99·8 ± 0·1 per cent. Powdered samples of the appropriate composition were evaporated from a platinum boat on to $\frac{3}{4}$-mil polyethylene sheet. The thickness of the film of lithium fluoride as measured by the a.c. conductivity of a known volume of distilled water in which a fiduciary portion of the film plus sheet had been steeped, was about 0·2μ. Infra-red spectra were obtained by use of a Perkin–Elmer 'Model 21' double-beam spectrophotometer with a cæsium bromide prism.

Fig. 1 shows the results for the wave-length of the transmission minimum as a function of isotopic composition. Each circle represents a separate sample. The straight line is drawn through 32·6μ, the accepted value[2] for the fluoride of natural lithium (92·5 per cent lithium-7, 7·5 per cent lithium-6), with a slope such that the ordinates of the end-points are inversely proportional to the square root of the reduced masses of ^{6}Li^{19}F and ^{7}Li^{19}F, that is, 1·059. The best straight line fitting the results is a trifle steeper. Our estimate of the infra-red dispersion wave-lengths for 100 per cent enrichment is the following: ^{6}Li^{19}F, 30·8 ± 0·2μ; ^{7}Li^{19}F, 32·6 ± 0·2μ; ratio of wave-lengths, 1·058 ± 0·013. These values are in excellent agreement with those predicted recently by Stevenson and Nettley[3], namely, somewhat less than 30·9μ for ^{6}L^{19}F and somewhat exceeding 32·5μ for ^{7}Li^{19}F. Their values were deduced from measurements on the infra-red reflectivity of single crystals grown from fluorides made from enriched lithium.

The enriched isotopes were obtained and their analyses provided through Dr. P. S. Baker, Isotopes Division, Oak Ridge National Laboratory. We thank also A. G. Strelzoff and L. W. Hantel

Optically Active Fluorite Films

THE possibility of evaporating in vacuum an optically active film of an otherwise isotropic material, by oblique deposition on to a flat glass substrate revolving about its normal as an axis, is confirmed. The helically deposited fluorite films ranged up to about 18μ thick, and turned the plane of polarization of a normally incident beam by as much as 2·25° at $\lambda = 0{\cdot}546\mu$.

Films deposited obliquely upon stationary substrates are usually anisotropic[1], a fact which helps to explain the optical activity of a helically deposited film. Thus, a film which is built up upon a revolving substrate can be envisaged as an anisotropic plate the azimuth angle of the fast axis of which continuously increases with depth. In this grosser sense, a helically evaporated film would resemble a Solc filter of the fan type[2], were the retardation plates of the Solc filter to approach zero thickness (and infinite number) while maintaining the total thickness of the filter constant. This model for the behaviour of the helically evaporated films would predict an optical rotation as a function of wave-length which could be compared with that of helically evaporated films.

From the point of view of the microstructure of the film, however, where the dielectric constant and hence the refractive index would depend upon alignment of the film structure, the activity of a helically deposited film could be due to the co-operative action of a helically symmetrical arrangement of crystallites, crystal growth or voids.

Experimental data were obtained for fluorite films which were deposited on circular microscope cover glasses. These were sprung against a relatively massive metal disk intended to minimize local differences of temperature, and to retard heating of the substrate by the vapour source. The metal disk, in turn, could be mounted on any one of three parallel shafts extended from the pinions of an electric-clock motor in the vacuum system, each turning at a different angular velocity. While spinning attached to the metal disk, the substrate was normally shielded from the vapour source by a corrugated brass shim-stock shutter less than an inch away. The shutter was operated by a rotary solenoid in the vacuum system energized through a switch on the fastest motor shaft and relays arranged so that the substrate would be exposed to the vapour source for an integer number of turns.

Evaporation was carried out at residual pressures no higher than 0·3μ mercury, the limit pressure due to outgassing of the motor and solenoid being about 0·1μ mercury. The vapour source was a molybdenum boat, in which about 0·5 gm. of synthetic crystal fluorite scraps were melted. The altitude angle of the vapour source with respect to the substrate was between 30° and 60°.

A Fizeau interferometer was used for measuring the optical thickness of each fluorite film. The optical activity of the film was measured using an *ETL–NPL* automatic polarimeter connected to a potentiometric chart recorder. In the presence of any birefringence in a sample film an oscillatory trace is obtained when the sample is rotated in azimuth. The mean angular rotation $\bar{R}$ of each film was taken as the interval, in angular units, between the chart record in the absence of a sample, and the mean value of at least four cycles of the oscillatory trace obtained from a helically deposited sample film. The birefringence which caused the oscillatory trace was expressed in terms of the maximum value of the ratio $(\bar{R} - R)/\bar{R}$, where $\tilde{R}$ is the optical rotation measured as a function of azimuth angle. The mean birefringence of all the samples was 19 per cent.

Measurements with the automatic recording polarimeter were always completed within a few minutes after deposition of the film. It was found that the optical activity of the helically deposited fluorite films decays a few per cent in the first day, but after several months rises.

It was found that the hand of the optical activity was always related to the hand of the substrate in the same way. Thus, a left-hand helically deposited film was always dextro-rotatory, and *vice versa*. Thus, as a ray travels through the film, the azimuth of the film and of the plane of polarization advance in opposite senses.

The relative advance of the plane of polarization of a ray crossing the film to the advance of film azimuth can be expressed by an advance ratio N_a. This advance ratio, $N_a = \bar{R}/360T$, for a number of helically evaporated films has been plotted against the film pitch P in Fig. 1.

Birefringence of the films was found to be smaller when an integral rather than a fractional number of turns were deposited. Considerable effort was spent trying to improve the constancy of vapour emission,

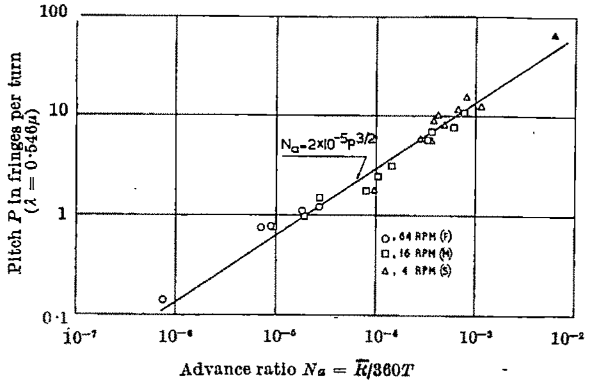

Fig. 1

as larger birefringence seemed to be associated with larger wedge angles in the completed film. Among other possible causes of the birefringence are the properties of the film at its boundaries or the presence of stresses.

For example, the properties of the film at the fluorite–air and the fluorite–glass interfaces cannot be expected to match those of the interior of the film.

The highest value of the specific optical activity reached in the experiments was 155°/mm. assuming a refractive index of 1·25 for the helically deposited fluorite film.

CHEMISTRY

Effect of Tartar Emetic on the Growth of Ammonium Dihydrogen Phosphate Crystals

THOUGH there are numerous examples of changes of habit in crystals produced by impurities in the mother liquor, it has scarcely been noticed that crystal habits are so changed by optically active impurities as to appear to be modified, due to the asymmetric structures of the impurities. Tartar emetic has been found to be one of such impurities which influence the growth of crystals of ammonium dihydrogen phosphate.

When optically inactive substances take part in the growing of the two faces which have the reflecting plane as the single element of symmetry, they are adsorbed on both faces in the same manner and so should influence the growth of the faces symmetrically. On the other hand, in the case of optically active impurities, even if they are adsorbed on one face, either they cannot be adsorbed on the other, or they may be adsorbed in a different manner, and consequently the effect may be different on the two faces.

A crystal of ammonium dihydrogen phosphate has bipyramidal and prismatic faces as shown in Fig. 1. It belongs to the tetragonal scalenohedral class, and the two adjacent pyramidal or prismatic faces are symmetric only with respect to the plane containing the Z axis and one of the two diagonal axes, P_1 and P_2. The two diagonal axes are distinguished by piezoelectric tests, and, after Mason[1], P_1 is taken as the axis along which a tension produces a positive charge at the positive end of the Z axis. But, so far as the habit is concerned, ammonium dihydrogen phosphate appears to be so highly symmetric that no difference can be observed in the behaviour among the faces of each form not only in pure solution but also in solutions containing various metal ions which are known to influence the crystal growth. This is due to the fact that the substances adsorbed on the growing faces are all optically inactive.

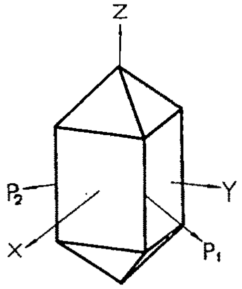

Fig. 1. Crystal form and crystal axes of ammonium dihydrogen phosphate

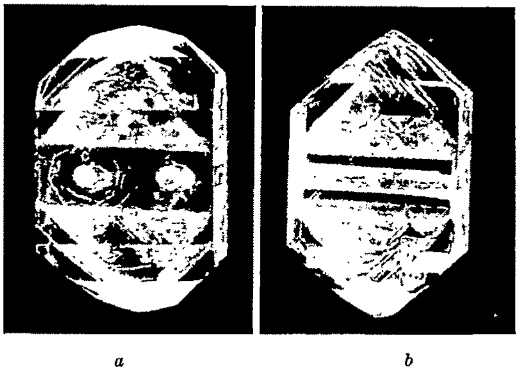
Crystals of ammonium dihydrogen phosphate were allowed to grow in solutions containing *d*-tartar emetic in different concentrations for one or two days at about 38·5° C. The temperature of each solution was kept 1 deg. C. lower than saturation point. In the lower concentration-range, the growth-rate of the pyramidal faces decreased gradually with increasing concentration, but there was no difference between the rate of growth of the (101) and (011) faces. When the concentration reached 3×10^{-3} M, peculiar changes were observed. Figs. 2*a* and *b* show photographic views of a crystal along the X and Y axes respectively. The summits of the bipyramid are rounded. The natural pyramidal faces develop only partly from the edges of the adjacent prismatic faces, and the area of the (011) faces is very much diminished. The growth-rate of the (011) faces decreases to 70 per cent of that measured in the solution without impurities; on the other hand, that of the (101) faces drops to 12 per cent. The former is equal to the value extrapolated from the results in the lower concentration-range.

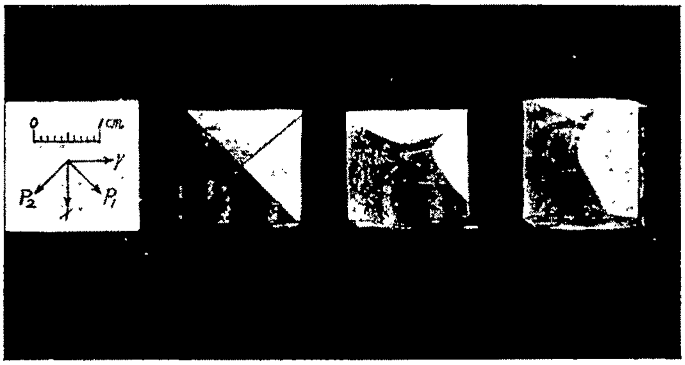


a *b*

Fig. 2. Effect of *d*-tartar emetic on an ammonium dihydrogen phosphate crystal; *a*, viewed along the X axis; *b*, along the Y axis. Two holes were drilled through the crystal for mounting on a crystal holder

Next, in place of *d*-tartar emetic, *l*-tartar emetic was added to the solution at the concentration of $3 \times 10^{-3} M$, and the crystals were grown in the same conditions as described above. The *l*-compound appears to have an effect symmetrical to that of the enantiomorph.

Fig. 3 shows the pyramidal faces of the crystals obtained from three different sources, which are viewed along the Z axis in the position shown at the left side of the figure. *a* shows the normal form obtained from the pure solution, *b* and *c* the effects of *d*- and *l*-tartar emetic respectively. Bright faces correspond to ($\bar{1}$01) and (011) of each crystal. In Fig. 3*c* the (101) faces become small in area, and the (011) faces develop laterally as a result of marked retardation in the vertical growth. Each of the faster faces, (011) in Fig. 3*b* and (101) in Fig. 3*c*, forms a triangle with a round corner at the opposite position to the edge of the adjacent prismatic face. The locus drawn by the corner during growth appears as the ridge from the apex of the pyramid to that of the face. The direction of the ridges made by *d*-tartar emetic inclines, as shown in Fig. 3*b*, anticlockwise from the Y axis to the P_2 axis, and that by *l*-tartar emetic clockwise from X to P_2 as shown in Fig. 3*c*. In this manner, the habits of ammonium dihydrogen phosphate modified by *d*- and *l*-tartar emetic are symmetrical with respect to the planes of symmetry of the crystal.



a *b* *c*

Fig. 3. Pyramidal faces of ammonium dihydrogen phosphate crystals obtained from three kinds of solutions; *a*, without impurities; *b*, containing *d*-tartar emetic; *c*, containing *l*-tartar emetic, viewed along the Z axis in the position shown at the left side

Tartar emetic in aqueous solutions dissociates into the potassium and antimonyl tartrate ions. The former showed no effect on the growth of an ammonium dihydrogen phosphate crystal. The latter forms a stable complex ion which is scarcely hydrolysed in neutral or weakly acid solutions. Therefore the effect of tartar emetic should be due to the complex ion. Actually no change in habit was observed in the solution containing hydrochloric acid besides tartar emetic. This shows that the complex ion is decomposed and made ineffective. Since the tartrate ion has in itself no effect on the crystal growth, the antimonyl tartrate ion must be adsorbed on the crystal face through the action of the antimony atom or of the group surrounding it.

High-Temperature Oxidation of Zinc Sulphide

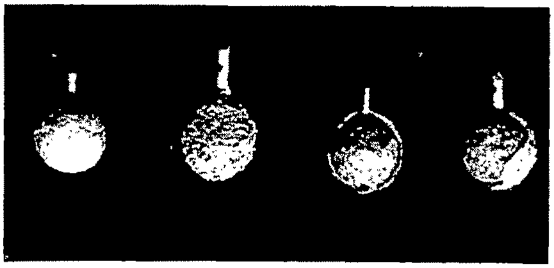
In earlier work[1] the rate of oxidation of the 110 faces of zinc sulphide was measured by use of a thermobalance. Below 830° C. the rate was found to be 'chemically controlled', being an exponential function of temperature and largely independent of the thickness of the product layer of zinc oxide. Above 830° C. there were indications of the onset of a 'diffusion control', depending on the diffusion of the oxygen up to the zinc sulphide interface through the layer of porous oxide.

In the present work we are extending these studies into the range 1,000–1,500° C. We find that above 1,150° C. the formation of zinc oxide no longer occurs on the surface of the zinc sulphide, but occurs instead at some distance from the surface in the gaseous phase.

A sphere of compressed zinc sulphide powder was suspended on a thread in a vertical tubular furnace. At $t = 0$ a nitrogen atmosphere surrounding the sphere was replaced by a stream of air. After a short period of reaction the sphere was removed and was found to be surrounded by a complete but very fragile concentric shell of oxide. Fig. 1 (*a*–*d*), referring to a temperature of 1,250° C. and a reaction-time of 1 min., show respectively a sphere before oxidation, a sphere after removal from the furnace and two spheres from which the shell has been partially removed. The gap between the oxide shell and the underlying zinc sulphide is clearly visible.

The vapour-pressure of the sulphide at high temperatures has been measured by Veselovski[2] and by Richards[3]. The latter has shown that the vaporization probably occurs with dissociation into zinc and sulphur. In our experiments it appears that these substances diffuse outwards from the surface of the sphere and meet oxygen diffusing inwards, thus giving rise to a deposit of zinc oxide at an approximately spherical and concentric reaction zone. As might be expected from the increasing volatility of the sulphide, the distance between the shell and the core increases with rising temperature and may be greater than 1 mm. over 1,300° C. (but depends also on the rate of air flow). The shell diameter appears always to be greater than the original core diameter, and the shell may perhaps have grown downwards from the support. The mechanism of the process thus appears to be similar to that of the diffusion flame surrounding a burning oil droplet.

Determinations of the rate of the oxidation process are being made by measurement of the rate of



(*a*) (*b*) (*c*) (*d*)

Fig. 1

evolution of sulphur dioxide. Our theory indicates that the reaction-rate per unit area may be expected initially (that is, before any significant thickness of shell has been formed) to vary inversely as the particle diameter and directly as the half-power of the Reynolds number (which determines the thickness of the boundary layer) together with a function of the temperature.

Separation of *m*-Xylene and *p*-Xylene by Gas Chromatography

Considerable interest has recently been centred on the difficult separation of *m*-xylene and *p*-xylene by gas chromatography both from the point of view of the analysis of mixtures containing these isomers and the assessment of the performance of high efficiency columns. Martin and James[1] predicted some years ago that it should be possible to achieve a separation using benzyldiphenyl as a stationary phase with a high-efficiency column and this was recently demonstrated by Zlatkis[2]. Similar partial separations have been described[3–5] with other stationary phases in long packed columns and by using long capillary columns[6]. Langer[7] has described the use of tetrahalophthalic esters as stationary phases which cause the meta isomer to be eluted before the para—the reverse of the usual order. (In an earlier paper[8], the relative retention volumes of *p*-xylene and *m*-xylene were incorrectly quoted in the reverse order for both *n*-hexatriacontane and benzyldiphenyl.)

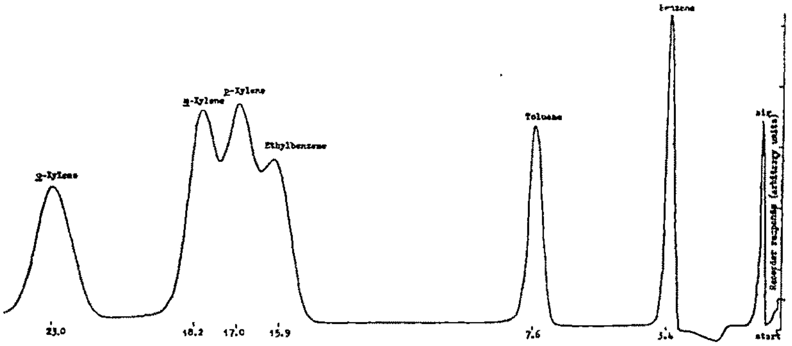
We have found that the aromatic nitrogen compound 7,8-benzoquinoline produces a better separation of the xylene isomers than any other stationary phase previously reported.

Table 1 shows retention-volume results at 78·5° C. for three established stationary phases and 7,8-benzoquinoline. Separation factors for *m*-xylene/*p*-xylene and *p*-xylene/ethylbenzene are also given together with the number of theoretical plates computed from Glueckauf's chart[9] required to bring about a separation of equimolar amounts of the isomers with a fractional impurity of 0·1 per cent in each band.

Table 1. Retention Volume Data at 78·5° C.

Index	Squalane	Benzyl-diphenyl	Tritolyl-phosphate	7,8-Benzo-quinoline
Relative retention vol. (benzene = 1)				
Toluene	2·513	2·342	2·299	2·473
Ethylbenzene	5·334	4·925	4·654	5·282
p-Xylene	5·975	5·242	4·934	5·639
m-Xylene	6·128	5·483	5·062	6·091
o-Xylene	7·307	6·858	6·494	7·827
Specific retention volume for benzene (ml./gm.)	95	91	86	78
Separation factor *p*-Xylene/ethylbenzene	1·120	1·064	1·060	1·068
Separation factor *m*-Xylene/*p*-xylene	1·025	1·046	1·026	1·080
Number of theoretical plates to effect 99·9 per cent purity (after Glueckauf) of *m*/*p*-xylene	60,000	20,000	55,000	7,000

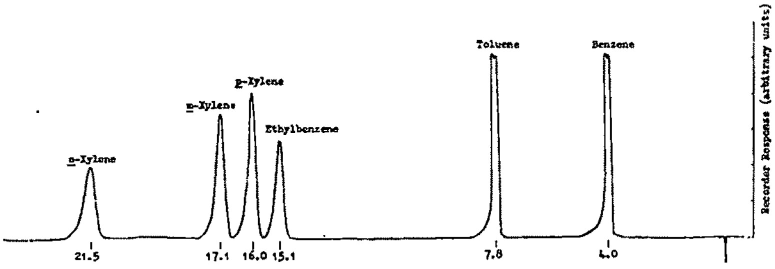
For comparison purposes, values from the literature of the separation factors for *m*-xylene/*p*-xylene are given in Table 2 together with the relative volatility at the operating temperature employed.



Time (min.)

Fig. 1. Separation of aromatic hydrocarbons on packed column:

Column	120 cm. × 0·4 cm. internal diameter
Column temperature	78·5° C.
Column packing	20 per cent weight 7,8-benzoquinoline on 72–100 mesh 'Celite' 545
Weight of packing	5·0231 gm.
Carrier gas	Nitrogen
Inlet pressure	111 cm. mercury
Outlet pressure	Atmospheric
Rate of flow	42 ml./min.
Size of sample	1 μl.
Efficiency	1,600 theoretical plates (*o*-xylene)
Detector	Martin gas density balance



Time (min.)

Fig. 2. Separation of aromatic hydrocarbons on capillary column:

Column	12 m. × 0·25 mm. internal diameter copper capillary coated with 12 mgm. 7,8-benzoquinoline
Temperature	78·5° C.
Carrier gas	Nitrogen
Inlet pressure	3 lb./in.^{2}
Rate of flow	0·7 ml./min.
Size of sample	Approximately 1 μgm.
Efficiency	14,600 theoretical plates (*o*-xylene)
Detector	Flame ionization

Table 2. SEPARATION FACTORS FOR m-XYLENE/p-XYLENE

Stationary phase	Temperature (° C.)	Separation factor	Relative volatility
n-Octadecane (ref. 1)	65	1·012	1·050
Paraffin wax (ref.1)	78·6	1·008	1·033
Lubrol Mo (ref. 1)	78·6	1·025	1·033
Benzyldiphenyl (ref. 2)	100	*ca.* 1·032	1·033
PEG(300)Dibenzoate (ref. 3)	65	1·038	1·050
PE Glycol (ref. 4)	*ca.* 50	1·035	1·065
Dodecylphthalate (ref. 6)	40	1·021	1·053
Di-n-propyl-tetrachlorophthalate (ref. 7)	110	0·962	1·033

7,8-Benzoquinoline offers a much easier separation of the xylenes while maintaining the ability to separate ethylbenzene from them. Fig. 1 shows the resolution achieved on a 4-ft. column having an efficiency of 1,600 theoretical plates. The isomers are completely resolved on a capillary column 12 m. long (Fig. 2).

The mechanism of this separation is obscure, but the configuration of the stationary phase molecule appears to be more significant than the presence of the nitrogen atom. Phenanthrene, the parent hydrocarbon necessarily used at a higher temperature above its melting point, shows similar results to 7,8-benzoquinoline at the same temperature (Table 3).

Table 3. COMPARISON OF 7,8-BENZOQUINOLINE, PHENANTHRENE AND BENZYLDIPHENYL AT 110·8° C.

Index	7,8-Benzoquoline	Phenanthrene	Benzyldiphenyl
Relative retention volumes (benzene = 1)			
Toluene	2·23	2·39	2·12
Ethylbenzene	4·28	4·61	3·96
p-Xylene	4·65	5·07	4·20
m-Xylene	4·90	5·35	4·37
o-Xylene	6·04	6·57	5·36
Specific retention for benzene (ml./gm.)	31	36	41
Separation factor m-Xylene/p-xylene	1·053	1·053	1·040
Separation factor p-Xylene/ethylbenzene	1·088	1·101	1·061

Rapid Specific Method for Determination of Aldosaccharides in Body Fluids

IN the clinical field it is of importance to have a rapid and exact method for glucose determinations. In order to avoid the non-specific reduction methods, a coupling reaction was worked out utilizing the conjugation of aldoses and ketoses with meta-aminophenol in acetic acid. After some preliminary experiments[1], a routine method was described[2]. The method has been used for some time in this laboratory and has proved satisfactory; but, because of the necessarily long boiling time of 30 min., and the fact that the whole range of urine sugar concentration cannot be read without dilution of the urine, it was considered an advantage to have a reagent giving a more rapid reaction and a wider range. Many aromatic amines have been tested; of these, one of the most suitable was *ortho*-toluidine, for which the optimal boiling time is 8 min. (Fig. 1). It gives a blue-green colour with maximum absorption at 6250 A. and is fairly specific for aldosugars (Fig. 2). Blood treated with glucose oxidase gave readings corresponding to 0–4 mgm. glucose per 100 ml. blood. With this reagent glucose quantities of 10–400 μgm. can be read directly in a Beckman *B* photometer.

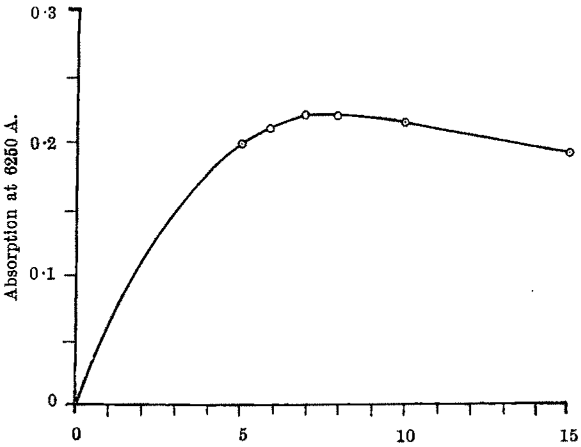

Fig. 1. Absorption of glucose colour after different times of boiling

Procedure for blood. 0·1 ml. whole blood is rinsed into 1 ml. of 3 per cent trichloracetic acid. After centrifugation, 0·2 ml. of the clear supernatant is mixed in a test-tube with 3 ml. of a 6 per cent solution of *ortho*-toluidine in glacial acetic acid. The tubes are placed in a boiling water-bath for 8 min., cooled, and read against a reagent blank at 6250 A. Standard glucose solutions are boiled together with every series. The procedure is the same as for blood. Blood sugar

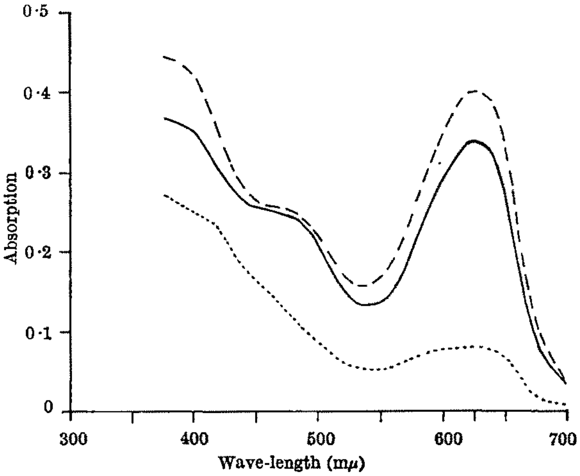

Fig. 2. Absorption spectra of the colour developed by different hexoses read in a Beckman *DK* photometer. ——, Glucose; – – – –, galactose; . . . . , lævulose

up to 800 mgm. per cent can be determined in this way. In a Beckman *B* photometer values down to 20 mgm. per cent can be read and still lower concentrations by changing the dilution of blood with trichloracetic acid. Serum or plasma can also be used. In this case protein precipitation is not necessary.

Procedure for urine. 0·004 ml. urine (measured with a micro-pipette[3]) plus 3 ml. of a 2 per cent solution of *ortho*-toluidine in acetic acid are boiled for 8 min., cooled and read against a reagent blank at 6250 A. and compared with standard glucose solutions. Benzoic acid does not interfere with the reaction and may safely be used as a preservative.

The reaction is very sensitive to water. The concentration of water should not exceed 10 per cent.

Technical grade *ortho*-toluidine is a brown solution which should be purified by distillation at ordinary pressure. The distillate is slightly yellow. The first 80 per cent of distillate is pure enough for direct use and seems to be stable for months, if kept in the dark. We use the Riedel de Haen product; but the practical grade *ortho*-toluidine (Eastman) is also suitable. The pure *ortho*-toluidine ('from nitrate') (Eastman) could be used directly without distillation.

The acetic acid should be of pure analytical quality. Both Riedel de Haen and 'Analar' products were used successfully. The reagent should be made fresh every day. If an automatic pipette is used for the reagent it should be all glass, as we have found the reagent to give false coloration with traces of metals.

Other aromatic amines tested could be used in a similar way. 2 : 6-Dimethyl aniline gave a similar absorption curve and was nearly as sensitive as *ortho*-toluidine to glucose but less sensitive to galactose; 2 : 5-dimethyl aniline gave lower values but was more sensitive to galactose than to glucose. Specific galactose determinations could possibly be made in this way.

The investigation was supported by grants from Föreningen för sockersjuka i Stockholm, Konung Gustav V : s årsfond and Svenska Livförsäkringsbolagens forskningsfond.

Chemical Synthesis of Hexose and Hexosamine Sulphates

RECENT work[1] in these laboratories has been concerned with the enzymic degradation of naturally occurring aminopolysaccharide sulphates. Further extension of these studies necessitated the synthesis of a series of hexose and hexosamine sulphate esters. Methods for the sulphation of carbohydrates have been re-examined and procedures developed for the synthesis of authentic samples of glucose-6-sulphate and N-acetylglucosamine-6-sulphate.

In the following experiments carbohydrate sulphate esters were isolated as their barium salts, but for the purpose of paper chromatography and afterwards, preparative column chromatography on cellulose, these were converted to the free acids by passage through 'Dowex 50' (H^+ form) columns and then concentrated by distillation under reduced pressure and lyophilization.

Paper chromatography was carried out on Whatman 3*MM* filter paper using downward irrigation with butan-1-ol/acetic acid/water, 50 : 12 : 25, as solvent. Spots were made visible by spraying with alkaline silver nitrate or aniline hydrogen phthalate[3], and with Elson–Morgan reagents[4] for hexosamines. Ester sulphates were detected by a modification of the method due to Burma[5]. The technique used in chromatography on cellulose columns was essentially that of Putman[6], the developing solvent again being butan-1-ol/acetic acid/water, 50 : 12 : 25.

Direct sulphation of glucose with chlorosulphonic acid[7,8] yielded a heterogeneous product. Paper chromatography indicated the presence of three components, one identical with glucose, while the others contained ester sulphate. Column chromatography of the mixture yielded three peaks of reducing substance, the first of which was shown to be pure glucose. Analysis of the substances constituting the remaining peaks indicated that they corresponded to pure glucose monosulphate and disulphate respectively.

Definitive synthesis of glucose-6-sulphate was attempted using a method originally evolved for the preparation of glucose-6-phosphate[9]. Glucose was converted to 1,2,3,4-tetra-O-acetyl-β-D-glucose via 6-O-triphenylmethyl-1,2,3,4-tetra-O-acetyl-β-D-glucose using Reynolds and Evans's method[10]. The 1,2,3,4-tetra-O-acetyl-β-D-glucose was sulphated with chlorosulphonic acid and the product examined by paper chromatography. Two components were obtained, one identical with tetra-acetylglucose, and the other containing ester sulphate. Isolation of the components by column chromatography indicated the first member of the mixture to be pure tetraacetylglucose, while the second gave analysis figures which were consistent with it being 1,2,3,4-tetra-O-acetyl-β-D-glucose-6-O-sulphate. The latter was deacetylated by heating under reflux with 1 per cent acetic acid for 2 hr. Paper chromatography of the product indicated the presence of two components, one identical with glucose and the other containing ester sulphate. The latter was isolated by column chromatography and converted to the barium salt. On analysis it was shown to be pure barium glucose monosulphate. From the method of preparation this would appear to be authentic glucose-6-sulphate. The properties of barium glucose monosulphate, prepared by direct sulphation of glucose were identical with barium glucose-6-sulphate prepared by definitive synthesis.

The successful preparation of authentic glucose-6-sulphate by the above route suggested that a similar technique might be employed in the preparation of authentic N-acetylglucosamine-6-sulphate.

N-acetylglucosamine was prepared by Roseman and Ludoweig's method[11] and converted to 1,3,4-tri-O-acetyl-N-acetyl-β-D-glucosamine via 6-O-triphenylmethyl-1,3,4-tri-O-acetyl-N-acetyl-β-D-glucosamine by the method of Anderson and Percival[12]. The tri-O-acetyl-N-acetyl compound was sulphated as before and the products of reaction examined by paper chromatography. Two components were obtained, one identical with the starting material and the other containing ester sulphate. The latter was isolated by column chromatography and shown, by analysis, to be 1,3,4-tri-O-acetyl-N-acetyl-β-D-glucosamine-6-O-sulphate. After removal of acetyl groups by hydrolysis with acetic acid, paper chromatography indicated the presence of two components, one identical with N-acetylglucosamine and the other containing ester sulphate. The latter was isolated as the barium salt after column chromatography and gave analysis figures consistent with a structure of barium N-acetylglucosamine-6-sulphate. Barium N-acetylglucosamine-monosulphate, prepared by the direct sulphation of N-acetylglucosamine, was identical with barium N-acetylglucosamine-6-sulphate prepared by definite synthesis.

Further evidence as to the location of the sulphate group in position 6 of the hexosamine molecule was obtained by examining the behaviour of the compounds in the Elson–Morgan reaction[13]. Both authentic N-acetylglucosamine-6-sulphate and N-acetylglucosamine monosulphate gave 100 per cent colour production in this test using N-acetylglucosamine as standard. It has been shown that N-acetylhexosamines substituted in position 6 behave normally in the Elson–Morgan reaction whereas substitution in position 3 results in enhanced colour production. On the other hand, substitution in position 4 causes suppression of colour formation[14]. N-acetyl galactosamine monosulphate, prepared by direct sulphation of N-acetyl galactosamine[11], also gives 100 per cent colour formation in the Elson–Morgan test[13], providing preliminary evidence of the location of the sulphate group in position 6 of the molecule.

A more complete account of this work, together with the results of enzyme studies, will be given elsewhere.

I am indebted to the Empire Rheumatism Council for a research fellowship, and to Prof. J. Pryde and Dr. K. S. Dodgson for advice and encouragement during the course of the above work.

Optical Rotation and Configuration of Poly-L-tyrosine

In a recent communication from this laboratory[1] it was reported that the constant b_0 in Moffitt's equation[2] for the optical rotation of a helical polypeptide is positive for solutions of poly-L-tryosine in dimethyl formamide and in pyridine, and for the sodium salt of this polymer in solution and in films. It was implied that in spite of the unusual sign of b_0 the polymer was in the α-helical form, and that the positive value is a consequence of the strong chromophoric group near the β carbon atom. We have since made further measurements of the optical rotation of a solution of this polymer in *N* sodium hydroxide and of films cast from a solution in dimethyl formamide at 60° C., together with observations of the infra-red spectrum and X-ray diffraction pattern of the films. These studies have led us to the conclusion that it is more probable that in dilute solutions in pyridine, in dimethyl formamide, and in aqueous alkali, poly-L-tyrosine is in the random coil configuration, as is its sodium salt in films.

The optical rotatory dispersion results are difficult to interpret unambiguously, because of the unknown effect of the chromophoric groups in the side-chain. There is no reason for supposing that the λ_0 of the Moffitt equation will be the same as in other polypeptides, that b_0 will be zero for a random coil arrangement, or indeed that the Moffitt equation will hold at all. However, if one nevertheless takes the usual value of 2120 A. for λ_0 and makes a Moffitt plot, one obtains values of b_0 of about $+300°$ for a solution in pyridine, about $+400°$ for solutions in dimethyl formamide and in *N* sodium hydroxide, about $+550°$ for films of the sodium salt, and about $-4000°$ for films of poly-L-tyrosine cast from dimethyl formamide. It is tempting to suppose that the configuration is different in the last case from that in the others, although the criterion is somewhat arbitrary. The distinction between the films cast from dimethyl formamide and the other systems gradually becomes less clear-cut as λ_0 is increased; however, so far as can be seen from measurements over a rather limited range of wave-length, the Moffitt plot gives the straightest line for a λ_0 of rather less than 2120 A.

Since at *p*H 14 the polymer is completely ionized, it would seem unlikely that the solution in aqueous alkali contains a large proportion of the α-helical configuration. On the other hand, infra-red spectroscopy and X-ray diffraction provide some evidence that the films cast from dimethyl formamide contain polypeptide in the α-helix form. Such films, when rolled, have been found to show marked infra-red dichroism of the kind associated with the α-helix. However, this behaviour is not reproducible, some similarly treated films failing to show any dichroism. The X-ray diffraction pattern of α-helices of poly-L-tyrosine packed hexagonally would be expected to have a strong ring corresponding to an interplanar spacing of 11·1 A., as may be calculated from the density of the films (1·254 gm./c.c.). The X-ray diffraction pattern of these films does indeed have a ring at 11·1 A.; but it is not particularly strong. Heating the films *in vacuo* at 130–140° C. for 2 hr. apparently crystallizes the polymer, and the subsequent X-ray pattern does show a strong 11·1 A. reflexion.

The results of these experiments are far from conclusive; but we feel that they strongly suggest that poly-L-tyrosine in each of the three solvents we have used, and its sodium salt in films, are in the random coil configuration, whereas in films cast from dimethyl formamide the polypeptide exists as α-helices.

We are indebted to Dr. T. Macdonald for taking the X-ray diffraction photographs in Courtaulds' X-ray Laboratory at Coventry.

BIOCHEMISTRY and PHYSIOLOGY

Peroxidases from Wheat Germ

A PREVIOUS communication[1] described the preparation of two crystalline hæmoproteins (556) and (566), which possess strong peroxidatic activity. It was found in later investigations[2] that both hæmoproteins form complexes with hydrogen peroxide and are not reduced with diphosphopyridine nucleotide or succinate in the presence of an active homogenate or particles from wheat germ. This indicates that both hæmoproteins (556) and (566) are peroxidases and thus can be called peroxidase (556) and (566), respectively.

In the previous work, peroxidase (566) was obtained in very low yield. When the first ammonium sulphate precipitate cake from wheat germ extract was kept for several months, only peroxidase (556) and no peroxidase (566) was obtained. However, in the direct spectroscopic examination of wheat germ after reduction with sodium dithionite the predominant band is at 560–570 mμ, and that at 556 mμ is very weak.

We have therefore adopted a new method for the preparation of peroxidase (566), as follows. Wheat germ, without pretreatment by organic solvents, was suspended in five volumes of 0·1 *M* phosphate buffer of *p*H 7·0 and squeezed by pressing through a cloth. The fraction of the filtrate precipitated between 20 and 60 per cent saturation with ammonium sulphate was dialysed. It was then adsorbed on 'Amberlite' *CG*–50 equilibrated at *p*H 6·5 with 0·02 *N* ammonium phosphate buffer. After elution with 0·25 *N* buffer of *p*H 7·0, the eluate—in which peroxidase (566) was present in relatively larger amount but which contained no peroxidase (556)—was again adsorbed on 'Amberlite' *XE*–64 and eluted successively with 0·15 *N* and 0·25 *N* buffer of *p*H 7·0. Both fractions were separately chromatographed on 'Amberlite' *XE*–64 resin columns using 0·075 *N* and 0·10 *N* buffer of *p*H 7·0, respectively. Crystalline peroxidase (566), which has an octahedronal form, was obtained from both main effluents in the same way as in the earlier methods[1] (Fig. 1).

Peroxidase (566) thus obtained forms a stable complex with hydrogen peroxide which cannot be identified with any of the established complexes. This complex has absorption peaks at 415 mμ, 540 mμ and 570 mμ (Fig. 2. The Soret peak was determined by means of a Beckman spectrophotometer). Peroxidase (556), however, forms a very labile complex similar to complex II. Peroxidase (556) and (566) may be identified with peroxidase II and I, respectively, prepared from horse radish by Theorell[3]. According to Keilin and Hartree[4] peroxidase I is a modified form of peroxidase II.

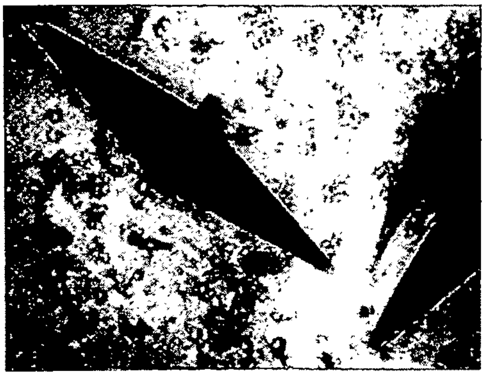

Fig. 1. Crystalline peroxidase (566). (Octahedron, × 200)

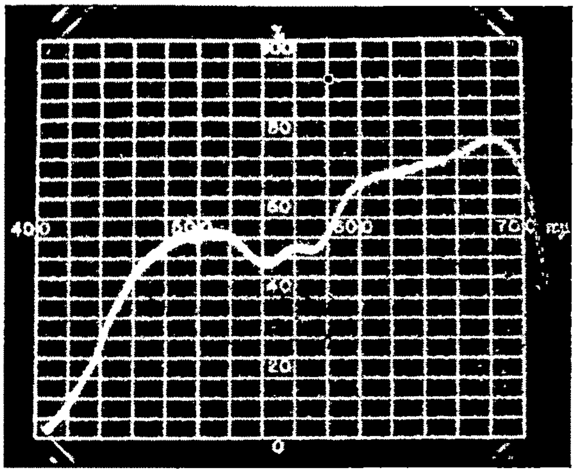

Fig. 2. Absorption spectrum of peroxidase (566)–hydrogen peroxide complex obtained with a rapid-scanning spectrophotometer. Reaction mixture contained about 0·5 per cent peroxidase (566), 0·005 *M* hydrogen peroxide and 0·06 *M* phosphate buffer of *p*H 6·0. The figure shows the spectrum of the complex in the visible region 5 min. after addition of hydrogen peroxide

Recently, Lundegårdh[5] obtained a peroxidase similar to peroxidase (556) from wheat roots treated with cold acetone. However, from the properties and behaviour during the preparation of the peroxidases, it seems that peroxidase (566) is the native protein, whereas peroxidase (556) is a modified form. Other properties of peroxidases (556) and (566) are being studied.

Factors affecting the Rate of Bilirubin Conjugation *in vitro*

THE conjugation of bilirubin to its glucuronides in rat liver homogenates was studied, using boiled liver extract[1], uridine diphosphoglucuronic acid (UDPGA), uridine diphosphoglucose (UDPG) with diphosphopyridine nucleotide (DPN+), or the system consisting of uridine triphosphate (UTP) with glucose-1-phosphate (G–1–P), and diphosphopyridine nucleotide as sources of the glucuronosyl radical. The effects of various substances on the formation of bilirubin glucuronides from bilirubin are listed in Table 1. Under the conditions used in these experiments, liver homogenates hydrolysed 5·7 per cent of added phenolphthalein glucuronide (0·42 m*M*) in 30 min., this hydrolysis being inhibited (44·5 per cent) by 5·5 m*M* potassium glucuronate, and even more

Table 1. BILIRUBIN CONJUGATION AS EXPRESSED BY THE FORMATION OF PIGMENTS GIVING A DIRECT DIAZO REACTION

Incubation mixture (3·6 ml.) contained 0·75 µmoles of bilirubin, 20 mgm. of serum albumin, 166 µmoles of *tris*(hydroxymethyl)aminomethane, 30 µmoles of magnesium chloride, homogenate corresponding to 0·2 gm. of wet liver tissue, and other constituents indicated in the table. *p*H measured at the end of incubation of 90 min. at 37° C. in air. Blank values (homogenate at the end of incubation) were subtracted

* *p*H maintained with *tris* buffer, *p*H 7·5.

† Incubation started with 83 µmoles *tris*, *p*H 8·2 after 30 min. 83 µmoles potassium phosphate at *p*H 6·9 was added in order to reach *p*H 7·5.

(90 per cent) by 1·1 m*M* boiled potassium hydrogen saccharate. Both these substances exhibited marked enhancing effects on the formation of a fraction of bilirubin giving the direct van den Bergh diazo reaction. Bacterial β-glucuronidase (100 units) added to the incubation mixture almost abolished the bilirubin conjugation. The acceleration of this conjugation by glucuronate offers a plausible explanation for the effect of treatment of neonatal hyperbilirubinæmia with glucuronic acid[2]. Lathe and Walker[3] reported an inhibitory effect of glucuronate on the synthesis of bilirubin glucuronide in rat liver slices. The liver slices technique shows results different in some respects from those obtained with whole-liver homogenates. Grodsky *et al.*[4], working with liver homogenates, and with methods essentially similar to those described here, reported that no hydrolysis of 2 × 10^{-5} *M* phenolphthalein glucuronide occurred in their experiments, and that no activation of bilirubin conjugation could be observed with saccharate. Brown *et al.*[5], referring to the experiments of Karunairatnam *et al.* (see ref. 5) with liver slices, also deny that β-glucuronidase plays any part in producing hyperbilirubinæmia of the new-born. It has now been clearly demonstrated that in neonatal jaundice the deficiencies of glucuronosyl transferase[3–5] and of uridine diphosphoglucose dehydrogenase[5] are essentially responsible for the increase of serum bilirubin-levels. Ethylenediamine tetraacetate increased the production of bilirubin conjugates.

4-Methyl-1,4-naphthoquinone, and the corresponding hydroquinone inhibited the formation of bilirubin glucuronides at a concentration of 10^{-4} *M*. Both also showed inhibition of the uridine diphosphoglucuronic acid dehydrogenase action. Vitamin K_1 ('Konakion', Roche) had negligible effect on bilirubin conjugation even at a concentration of 10^{-3} *M*. Menadiol diphosphate ('Synkavit') did not inhibit under these conditions. In the experiments with whole-liver homogenates it even showed an activating effect on the production of pigments reacting directly but in much higher concentrations (10^{-3} *M*) than used by Lathe and Walker[3] with liver slices, and only at *p*H's above 7. The mechanism of oxidative phosphorylation described by Clark, Kirby and Todd[6] has been suggested as a possible explanation of this activating effect. The diphosphate ester, of course, cannot be supposed to resist dephosphorylation by tissues after the injection.

Detailed reports will be published elsewhere[7].

Thanks are due to Mr. A. Jelínek (of this Institute) for his valuable technical assistance; to Sigma Chemical Co. (St. Louis, Mo.) for help and generosity in supplying uridine diphosphoglucuronic acid, uridine diphosphoglucose, diphosphopyridine nucleotide, adenosine triphosphate, uridine diphosphoglucose dehydrogenase, bacterial β-glucuronidase, glucuronic acid, and cysteine hydrochloride; to Hoffmann La Roche Co. (Basle), and to Léčiva, n.p. (Modřany) for their gifts of vitamin K analogues.

Preparation and the Hæmoglobin Content of Red Cell 'Ghosts'

STUDIES of species differences in red cell phosphatides[1] have led to a re-examination of the problem of standardizing the method of preparing erythrocyte membranes ('ghosts', post-hæmolytic residues). It seems essential that if results obtained with physical methods, for example, electron microscopy, are to be correlated with those obtained by chemical analysis, greater uniformity of procedure for preparation of membranes must be sought. The matter has received little recent attention. In what was perhaps the first chemical analysis of the structural protein, stromatin, Jorpes[2] found his preparations to contain irregular amounts of hæmoglobin, representing 10–30 per cent of the dry weight. Not long afterwards, Adams[3] offered spectroscopic evidence for the idea that in the intact cell hæmoglobin is combined with stromatin. Keilin and Hartree[4], however, were able to show that the finding was explained by the peculiar optical properties of the medium and could not be regarded as an indication of a hæmoglobin–stromatin complex. Since that time the blood-pigment found attached to 'ghosts' has come to be regarded, or, at any rate, treated, as a sort of contaminant the physical association of which with the membrane proper interferes with obtaining satisfactory material for analysis of other things. Various methods have been devised for preparing 'ghosts', one of which[5] claims to reduce the iron content to the vanishing point ($<0 \cdot 01$ per cent hæmoglobin). It is difficult to find information about the stage in the processing at which the intact membranes begin to break up, or, indeed, what the microscopic appearance of the final product is. Usually, the recommended techniques introduce acid or salt washing at some point to expedite the removal of hæmoglobin—measures which in our hands have led to prompt disintegration of 'ghosts', as shown by microscopic examination.

As an approach to a standard method for preparing intact 'ghosts', human whole blood was first taken into acid–citrate–dextrose, which has proved so satisfactory an anticoagulant for blood banks. The plasma was removed by centrifugation and the cells washed three times in saline at 4° C. Lysis and a number of successive washings in ten volumes of cold water were then carried out. Portions of 'ghosts' so prepared were lyophilized for analysis in terms of dry weight.

A simple direct method of measuring hæmoglobin in the dry 'ghosts' was devised by taking advantage of the ability of strong urea solutions to dissolve many fibrous proteins while not interfering with the absorption spectra of hæmoglobin and its derivatives[6]. Weighed amounts of lyophilized ghosts were dissolved in 40 per cent urea containing standard cyanide–ferricyanide and the concentration of cyanmethæmoglobin measured in a photometer.

It could be shown after four washings with water that of the total hæmoglobin found initially in the intact cells about 3 per cent remained attached to the 'ghosts'. Eight further washings with water did not appreciably lower the hæmoglobin content. It was calculated both from the total pigment in the washings and from the measurements in dried 'ghosts' that the loss of 'attached hæmoglobin' after the fourth wash was about 5 per cent. Moreover, during the eleventh and twelfth washings the 'ghosts' were allowed to stand in the cold water overnight. The gross volume, as estimated after each centrifugation, remained throughout at about two-thirds of the original volume of wet, whole cells. Frequent microscopic examination showed that the red cell membranes remained intact disks. As a result of these findings the routine was adopted of washing four times with ten volumes of water.

Blood samples from 18 healthy and sick people (including one with sickle-cell disease) were examined, and the amount of hæmoglobin attached to the 'ghosts' was found to be 49–57 per cent of the dry weight (mean 54 per cent). The ratio of hæmoglobin nitrogen to non-hæmoglobin nitrogen was about 2 : 1 and the molar ratio of phospholipid to hæmoglobin about 15 : 1.

The finding of fairly constant amounts of hæmoglobin attached to the 'ghosts' is at variance with most reports both in quantity and in regularity. To the objection that the pigment could represent merely a denatured insoluble deposit, it may be said that one of the methods for preparing oxyhæmoglobin from intact cells involves principally exposure to cold water. Moreover, 'ghosts' suspended in water were equilibrated with nitrogen and showed the colour change to be expected with the formation of substantial amounts of reduced hæmoglobin ; this was reversed on shaking in air. For the moment it would seem reasonable to suggest that the finding of hæmoglobin in fairly constant amounts in 'ghosts' prepared as above supports the idea that the pigment is indeed a component part of the membrane. The distortions of sickle-cells under reduced partial pressure of oxygen also argue for such a view. It is difficult to understand the effects except in terms of hæmoglobin bound firmly enough to re-arrange directly the shape of the membrane.

The method described gives with human blood morphological reproducibility of intact 'ghosts' at the level of the ordinary microscope and chemical reproducibility for the few things so far studied : hæmoglobin, nitrogen and phosphatide. Studies are now being made to determine in how far the method is suitable for blood of other species.

In vitro Synthesis of the Crown-Gall Tumour-inducing Principle

PREVIOUS research on crown-gall has shown that the transformation of normal plant cells into crown-gall tumour cells occurs in delimited stages involving specific causal agents[1].

Conditioning[2] requires several relatively simple compounds derived from the sap released by wounding the host. These include purines and possibly auxins[3], as well as other substances (Klein, unpublished work). Promotion requires auxin synthesized by the causal bacteria[4], from the incipient tumour cells[5], or from an external source. The nature of these auxins is under examination (Gentile and Klein, unpublished work).

The unique step in crown-gall formation is induction. This is normally accomplished by the action on conditioned cells of a tumour-inducing principle[6] synthesized by genetically competent bacteria[7]. Klein[8], Manigault *et al.*[9], Klein and Knupp[10], and Bender and Brucker[11], established that the bacteria synthesize the tumour-inducing principle, and succeeded in producing crown-gall in a variety of plants in the absence of the bacteria. Klein and Knupp demonstrated that the synthesis of the tumour-inducing principle *in vitro* was dependent on a synthesis factor present in wound juice. A survey of sources of the synthesis factor revealed that large amounts were present in malted barley[10]. The synthesis factor was extracted by salt solutions favouring the isolation of nucleic acids. When partially purified deoxyribonucleic acid from malted barley was added to a synthetic medium with 1 per cent sucrose as the carbon source, good growth of the bacteria and high titres of the tumour-inducing principle were obtained. Highly purified deoxyribonucleic acid from wheat germ was also a good source of the synthesis factor. By empirical substitution, the active material was found to be a pyrimidine, 5-methyl cytosine, its deoxyriboside, or its deoxyribotide, although thymine possessed slight activity.

Flasks of synthetic medium containing 5-methyl cytosine (100 μgm./ml.) were inoculated with log-phase cultures of *Agrobacterium tumefaciens* (strain B_6) and shaken for 24 hr. at 25° C. The culture medium was sterilized by centrifugation followed by filtration through a series of porcelain filter candles, and the filtrate treated with 3–4 volumes of 95 per cent ethanol. The resulting precipitate was dissolved in 0·2 *M* sodium chloride/0·01 *M* citrate, *p*H 7·0, and the solution dialysed overnight at 4° C. against the same buffer. It was reprecipitated with ethanol, dissolved in synthetic medium and sterilized by filtration. The procedure eliminated 'growth factors', including auxins, kinins, purines and pyrimidines, etc. Absorption spectra indicated that this purified tumour-inducing principle contained about 5 per cent nucleic acid by weight. The other major component was an acid polysaccharide which had no tumour-inducing principle activity. Further, the tumour-inducing principle activity of this purified preparation was abolished by deoxyribonuclease. The activity of the tumour-inducing principle was directly related to the known virulence of the strains of bacteria used, as well as to the concentration of the synthesis factor.

Treatment of properly conditioned disks of carrot phloem with purified tumour-inducing principle and subsequent promotion with auxin uniformly resulted in the formation of crown-gall tumours on the surface of all treated replicates (20–80 per cent variable). Time and temperature relations of this sterile induction are in conformity with the known course of tumour formation by bacteria *in situ*.

Details of this work are being prepared for publication elsewhere. It was supported by grants from the American Cancer Society and the Damon Runyon Memorial Foundation. Travel funds were supplied by the Rockefeller Foundation.

Blood-clotting Activity of the Venom of *Bothrops jararaca*

THE well-known blood-clotting activity of the venom from snakes of various species of the genus *Bothrops* has been attributed to its proteolytic activity[1], although Michl[2] (using paper electrophoresis) and Holz and Raudonat[3] (using fractional precipitation with ammonium sulphate) have presented evidence against this point of view. The latter authors obtained a fraction, which they called "Koagulin", with a strong blood-clotting activity but only slight proteolytic activity when hæmoglobin was used as substrate. More recently, it has been shown that there exist at least two proteolytic enzymes in the venom of *Bothrops jararaca*: one of them is thermolabile[4] and is precipitated at 50 per cent saturation with ammonium sulphate[5], while the other is stable to heat[4] and is precipitated at 70 per cent saturation with ammonium sulphate[5]. The latter enzyme has been isolated in a fairly pure state and has been called *Bothrops* protease *A* (ref. 6).

We have studied some aspects of the coagulating activity of the venom of *Bothrops jararaca* and tried to separate the coagulating factor from the known proteolytic activities of the venom. We verified that the coagulating activity varies considerably with the buffer used. In 0·2 *M* cacodylate buffer the activity reached a plateau at *p*H 6·5–7·4 and was higher than in any of the other buffers used (acetate, phosphate, citrate, *tris* – maleate and *tris* – hydrochloric acid). In phosphate buffer at *p*H 7 or more the clotting activity is inhibited. In 0·05 *M* cacodylate, *p*H 7·0, the activity was totally preserved for two months if the preparations were kept in a vacuum flask at 1° C. The clotting activity was measured using 0·10 ml. of the sample to which 0·20 ml. of oxalated horse plasma was added; the zero time was noted and the mixture was gently agitated in a water-bath at 35° C. until a firm clot was formed. The samples were always previously diluted with an equal volume of 0·2 *M* cacodylate buffer, *p*H 6·50, so that the final reaction mixture was at *p*H 7·0.

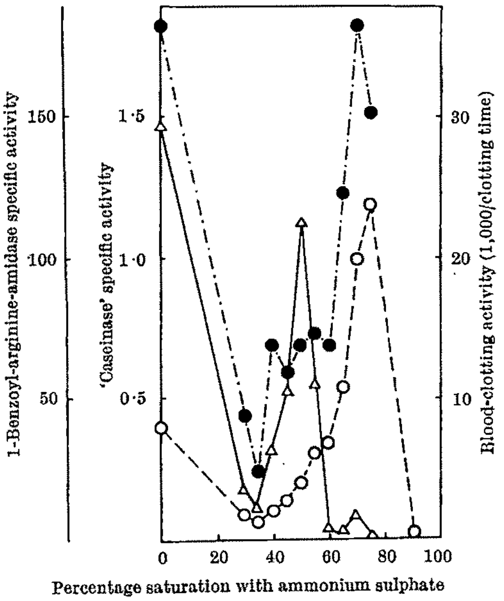

Fig. 1. Separation of protein fractions from *B. jararaca* venom by precipitation with ammonium sulphate: ○, 1-benzoyl-arginine-amidase activity; ●, blood coagulating activity; △, caseinase activity

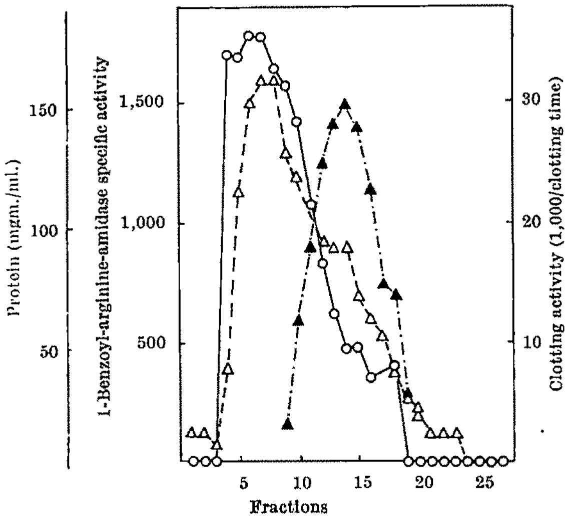

Fig. 2. Protein concentration, *Bothrops* protease *A* and blood-coagulating activities of fractions obtained by electrophoresis on a starch column of a crude preparation of *Bothrops* protease *A*. *Tris* buffer, pH 7·2, I 0·05. ○, 1-benzoyl-arginine-amidase specific activity; △, protein concentration; ▲, blood-coagulating activity

A 2 per cent solution of the venom in 0·05 M cacodylate buffer, pH 6·10 was fractionally precipitated with ammonium sulphate. The fractions obtained were dialysed against the same cacodylate buffer and assayed for 'caseinase'[6], 1-benzoyl-arginine-amidase and clotting activity; the latter was measured using the same amount of protein in all assays. The figures plotted in Figs. 1 and 2 were obtained by dividing 1,000 by the clotting time in seconds. As can be seen from Fig. 1 the peak of 'caseinase' activity separated between 40 and 50 per cent saturation with ammonium sulphate and the highest clotting activity was obtained in the fraction precipitated between 60 and 70 per cent saturation with ammonium sulphate. This fraction is probably identical with the "Koagulin" obtained by Holtz and Raudonat, although their coagulating fraction was precipitated at a lower level of saturation with ammonium sulphate. It can also be seen that the peak of 1-benzoyl-arginine amidase activity due to *Bothrops* protease *A* was found very near that obtained for the clotting activity, suggesting that the two activities were due to the same enzyme. We found, however, that electrophoresis on a starch column (Fig. 2) can separate these activities into two distinguishable peaks. It seems, therefore, that the clotting activity of *Bothrops jararaca* venom is neither related to its 'caseinase' nor to its *Bothrops* protease *A* content.

Glutaminase Activity of the Fœtal Membranes and Kidneys of Pigs

AT a Ciba Foundation Colloquium on the effects of ageing on electrolyte metabolism, Widdowson and McCance[1] reported the pH of allantoic fluid to be between 5·5 and 6 at 46 and 67 days of gestation. Ammonia accounted for about 25 per cent of the "titratable acidity + ammonia" of these fluids. The total osmolar concentration of the allantoic fluid had been shown before to be only one-third to one-half that of fœtal serum at the same times of gestation, mainly due to the low concentration of sodium in the fluid[2]. When, therefore, Widdowson and McCance found that the acidity of allantoic fluid was largely due to high concentrations of carbonic acid, they suggested that active sodium re-absorption by hydrogen-ion exchange might be occurring in the fœtal membranes and kidneys. In support of this, they reported considerable carbonic anhydrase activity in the fœtal kidneys and membranes lining the allantoic sac.

The appreciable amounts of ammonia in allantoic fluid suggested that it might be worth searching for glutaminase activity in these fœtal kidneys and membranes, for this enzyme is probably the main source of the ammonia found in the urine of more mature animals[3,4].

Table 1. AMMONIA PRODUCTION BY FŒTAL MEMBRANES AND KIDNEY SLICES

Tissue	Average percentage of tissue water	mgm. of NH_3-N produced per 100 gm. of dry tissue per hour	
		Substrate added	No substrate added
46 days gestation			
Mesonephros	86·2	205 (3)	119 (2)
Metanephros	92·1	382 (2)	42 (2)
Amniotic membrane	93·6	344 (3)	74 (3)
Allantoic membrane	91·9	144 (2)	39 (2)
Chorioallantoic membrane	95·3	476 (2)	112 (3)
90 days gestation			
Kidney	91·2	383 (4)	72 (4)
Amniotic membrane	93·4	388 (7)	93 (7)
Allantoic membrane	87·5	219 (4)	82 (4)
Chorioallantoic membrane	95·0	304 (8)	117 (7)
Adult sow			
Kidney	87·5	256 (7)	82 (5)
Adult rat			
Kidney	82·2	548 (4)	49 (3)

No. of estimations (each in duplicate) in parentheses

This has accordingly been done. The kidneys and membranes were taken from pig fœtuses of 47 and 90 days gestation, the kidneys sliced as soon after death as possible and the tissues frozen and kept at − 18° C. For measurement of glutaminase activity, the weighed tissues were incubated in Warburg vessels at 37° C. in oxygen for exactly 60 min. both with and without added l-glutamine in 0·015 M concentration and the resulting ammonia determined. The technique in general resembled that of Robinson[5]. The results are shown in Table 1. For comparison, the amounts of ammonia formed by slices of renal cortex of adult pigs and rats are also presented.

It is evident that there is considerable glutaminase activity, not only in the fœtal mesonephros and permanent kidney, but also in all the fœtal membranes. There was also some ammonia formation in the absence of added glutamine. Fœtal membranes, therefore, contain the enzymes to which the acidity and ammonia found in urine formed by more mature animals are thought to be due. These enzyme systems may therefore play as active a part in the elaboration of the fluids which the membranes enclose as the fœtal kidney itself.

An Iodine Compound associated with Albumin in the Plasma of Thyrotoxic Patients

A RADIO-IODINATED protein, other than labelled thyroglobulin, has been found in the plasma of patients receiving radioiodine therapy for thyroid carcinoma[1]. Although this protein was associated with the albumin fraction of plasma protein, immunological techniques differentiated it from iodinated serum albumin[2]. The protein was detected after tracer doses of radioiodine (0·31–1 mc.) and was found only in malignant conditions[1].

Recently, however[3], an iodinated protein associated with the albumin fraction on electrophoresis was reported in the plasma of a cretin given a tracer dose of iodine-131. An earlier report[4], which seems to have been overlooked, described the presence of a fraction of activity, apparently protein, associated with serum albumin in the plasma of thyrotoxic patients receiving radioiodine therapy. It is the purpose of this communication to report confirmation of this latter finding, by another method of analysis.

In human plasma, thyroxine is carried by a specific protein forming a complex which on electrophoresis migrates to a position intermediate between α_1- and α_2-globulin[5]. In plasma examined after iodine-131 therapy, labelled thyroglobulin may also be found and must be distinguished from labelled thyroxine carried by its specific protein because they migrate to the same position between α_1- and α_2-globulin. If thyroxine is present in high concentration some will be carried by albumin, and this complex must be distinguished from iodinated protein of the same electrophoretic mobility. 20 μl. of plasma containing a little sodium thiosulphate were subjected to paper electrophoresis[6]. After drying at 100° C., the paper was passed through an automatic scanning device which recorded the positions of radioactivity on the paper. It was then stained with a solution of naphthalene black in methanol to locate the bands of protein, and washed in a solution of 10 per cent acetic acid in methanol. As this procedure completely removes thyroxine from its carrier protein, the activity remaining on the strip is assumed to be iodinated protein. Thyroxine labelled with radioiodine added to normal plasma can be completely removed from an electropherogram of the plasma in this manner, as can labelled thyroxine from electropherograms of the plasmas of those thyrotoxic patients in which no iodinated proteins are found. Plasma samples shown by electrophoresis to contain the albumin component also showed on chromatography a peak of radioactivity at the origin, presumably due to an iodinated protein.

Radioactivity associated with the albumin zone after staining has been found in the plasma of six of the thirteen thyrotoxic patients examined after the administration of therapeutic doses of iodine-131 (7–25 mc.). In three cases the albumin-like compound was the only radioactive component found after staining and washing the electropherogram. In three others radioactivity was associated with both albumin and thyroglobulin fractions, and in one of these the albumin component was detectable five days after treatment, by which time labelled thyroglobulin had disappeared.

Biological Activity of L-Tryptophan Esters

ROZENDAAL *et al.*[1] have shown that dry crystalline L-tryptophan, when irradiated with fast electrons at doses up to 10^9 r., is partially transformed into a complex mixture of compounds from which it is possible to obtain by chromatographic separation a fraction which inhibits the growth of certain bacterial species.

We have attempted the fractionation of the same irradiated material (given to us by Dr. H. M. Rozendaal, General Electric Research Laboratories, Schenectady) and have isolated from it several compounds. About 20 per cent of the original L-tryptophan is transformed by the radiation into a complex mixture of compounds, some of which are in the form of free radicals—as can be demonstrated by the paramagnetic resonance spectrum obtained from the irradiated tryptophan.

Separation of the mixture into its components is still incomplete, and the results on this aspect of the problem will be the subject of a future publication.

In addition to the fraction described by Rozendaal we have obtained a different one, which has led to the finding that some tryptophan esters are active as growth inhibitors for several micro-organisms. This fraction (*WS* 55) was consistently obtained by elution from an alumina chromatographic column with *n*-butanol saturated with 1 *N* hydrochloric acid. Fraction *WS* 55 was purified and obtained in crystalline form from hot water after clarification with active charcoal ('Nuchar' *C*–190–*N*).

This compound has been identified as the *n*-butyl ester of L-tryptophan by comparison of its physical and chemical properties with synthetically prepared material[2] (Table 1).

Once the chemical structure had been established, it appeared that this compound could be formed simply as an artefact of the chromatographic technique and therefore does not necessarily have to be

Table 1. Elementary Analysis

	WS 55	Synthetic compound	Theoretical for *n*-butyl ester of L-tryptophan hydrochloric acid
C	60·21%	60·98%	60·66%
H	6·97	7·06	7·07
N	9·54	9·59	9·43
O (by difference)	11·21	10·94	10·78
Cl	12·07	11·81	12·01

Molec. wt. (by neutral equivalent)	305	301	297

considered as a product of X-irradiation of L-tryptophan.

Inhibition by this ester was demonstrated on the following micro-organisms: *Escherichia coli* B, *Bacillus subtilis* 6051, *Streptococcus mastitidis* V_9, and on representative micro-organisms of the following genera (these organisms have been tested by Dr. W. T. Bradner of our Division): *Bacteroides*, *Butyribacterium*, *Clostridium*, *Micrococcus*, and *Proprionibacterium*. Details of the bacteriological data obtained with the first three organisms have been presented elsewhere[3].

A series of higher homologues of esters of L-tryptophan were synthesized[2] and tested for antibacterial activity employing as test organisms *E. coli* B, and *B. subtilis* 6051. Quantitative determinations for growth inhibition were performed in minimal synthetic liquid medium[4]. The level of inhibition was measured by determining the turbidity in a series of flasks at 560 mμ after 16 hr. incubation at 37° C.

It can be seen from Fig. 1 that as the length of the alcohol chain increases, the amount of ester required for 50 per cent inhibition of growth decreases. Furthermore, increasing the alcohol chain to more than eight carbons does not further increase the antibacterial activity. Moreover, the methyl and ethyl esters showed no inhibitory activity at concentrations as high as 2 μmoles/ml. A similar quantitative relationship has been observed for *B. subtilis* 6051.

A number of esters of other amino-acids have been synthesized or obtained commercially and several of these in preliminary experiments have shown inhibitory activity against the test organisms.

As yet the mechanism by which these amino-acid esters interfere with the growth of micro-organisms is unknown. It is tempting to speculate on the possibility that the esters may interfere with protein synthesis by virtue of the fact that, since they are in a chemically 'activated' state, they might combine more readily than their parent amino-acid with a 'carrier' and thereby flood the protein-forming system with primarily an over-abundance of a single type of 'utilizable amino-acid complex'. This may cause inhibition of growth due to synthesis of unbalanced proteins.

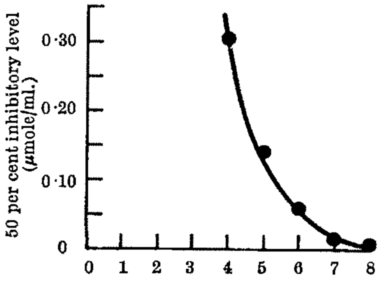

Fig. 1. Effect of alkyl chain-length of esters of L-tryptophan on the growth of *E. coli* B.

Detection of Sialic Acid in Various *Escherichia coli* Strains and in Other Species of Bacteria

It was recently reported[1] that an acidic aminopolysaccharide termed colominic acid was elaborated into the culture medium by the colocinogenic strain of *Escherichia coli* known as *K*235. This polysaccharide was afterwards shown to be composed of repeating units of *N*-acetylneuraminic acid or ovine sialic acid[2]. Since this was the first time that sialic acid substances had been found in other than mucopolysaccharides derived from mammalian sources a survey was made to ascertain whether these substances occurred in other *Escherichia coli* strains and in different species of bacteria. In addition, an attempt was made to correlate the pressure of sialic acid with other known properties of these bacteria.

A study of the agglutination properties of viable and heat-treated *Escherichia coli* $K235L+OC+$ bacteria in homologous antiserum revealed that this strain contains a capsule or envelope substance commonly termed a *K* antigen in addition to the somatic *O* antigen. Confirmation of the presence of a *K* antigen was obtained from agglutination experiments of viable bacteria in *K* antiserum.

The *Escherichia coli* $K235L+OC+$ strain was submitted for serological classification and showed the following serotype: *Escherichia coli* *O*1 : *K*1 : *HNM*. Several *Escherichia coli* strains of known serotype were analysed for sialic acid, bacteriocine and hæmolysin.

The bacteria were grown in sterile culture. The flasks, containing 500 ml. of suitable medium[2], were incubated with aeration at 37° C. for 5 hr. The bacteria were harvested by centrifugation. The cells were washed in 10 ml. of water and collected as before. The washed bacteria were suspended in 4 ml. of distilled water. The mixture contained in a sealed tube was heated for 2 hr. at 100° C. This procedure separated the *K* antigen from the bacterial surface. The bacteria were removed by centrifugation and the supernate decanted. Analyses for sialic acid were performed on this fluid by employing a modification of Werner and Odin's method[3].

The bacteria were tested for their ability to produce bacteriocine in the following manner. An overlay of nutrient soft agar seeded with *Escherichia coli* strain *B* bacteria was poured on to a stab culture of the organism grown on an agar plate and killed with chloroform. Presence of a bacteriocine inhibited the growth of the test organism, and a clear area about 2–3 cm. in diameter was visible around the killed stab

Table 1. *Escherichia coli* STRAINS TESTED FOR SIALIC ACID, BACTERIOCINE AND HÆMOLYSIN

Organism	Substance tested

E. coli O4 : *K*12(*L*) : *HNM*	−	+	+
E. coli O21 : *K*20(*L*) : *HNM*	−	−	−
E. coli O11 : *K*10(*L*) : *HNM*	−	−	−
E. coli O8 : *K*44(*A*) : *HNM*	−	+	−
E. coli O9 : *K*29(*A*) : *HNM*	−	+	−
E. coli O9 : *K*55(*A*) : *HNM*	−	−	−
E. coli O9 : *K*35(*A*) : *HNM*	−	−	−
E. coli O9 : *K*38(*A*) : *HNM*	−	−	−
E. coli O9 : *K*33(*A*) : *HNM*	−	−	−
E. coli O26 : *K*60(*B*6) : *HNM*	−	−	+
E. coli O127*a* : *K*63(*B*8) : *HNM*	−	−	−
E. coli O86*a* : *K*61(*B*7) : *HNM*	−	−	−
E. coli O111 : *K*58(*B*4) : *HNM*	−	+	−
E. coli O112*a*, 112*c* : *K*66 (*B*11) : *HNM*	−	−	−
E. coli O55 : *K*59(*B*5) : *HNM*	−	−	−

culture. Hæmolytic properties were determined by streaking the culture on blood agar plates and noting whether the colonies were surrounded by a greenish ring or by a cleared area.

The results of all tests are given in Table 1. It is to be noted that of 19 strains examined only two give positive tests for sialic acid. The positive test obtained with the *Escherichia coli O*10 : *K*5 : *HNM* strain was weak. A quantitative evaluation of the amount of sialic acid released to the supernate by the heat treatment of cells of this strain showed but one-tenth of the amount of sialic acid found in a similarly treated sample of *Escherichia coli O*1 : *K*1 : *HNM* bacteria. These results indicate that sialic acid is not a common component of the various *K* antigens found in *Escherichia coli* bacteria.

It will also be seen from Table 1 that six of the *Escherichia coli* strains tested produce bacteriocine and that three produce hæmolysin. However, the presence of these properties is unrelated to the occurrence of sialic acid in the cells. Two strains tested, *Escherichia coli O*6 : *K*53 : *HNM* and *O*4 : *K*12 : *HNM*, show both bacteriocine and hæmolysin activities. Several strains which are devoid of hæmolytic activity elaborate bacteriocine. In addition, strain *O*26 : *K*60 : *HNM* shows potent hæmolytic properties but is a non-producer of bacteriocine. Thus, the hæmolysin and bacteriocine activities of *Escherichia coli* strains are unrelated to each other.

Several strains of *Escherichia coli* containing the *K*1 antigen but with different *O* antigens were examined for sialic acid, bacteriocine and hæmolysin. The results are recorded in Table 2. It is to be noted that all 5 strains tested gave positive tests for sialic acid. In addition, three of these strains produce bacteriocine and none produce hæmolysin.

Table 2. *Escherichia coli* STRAINS CONTAINING THE *K*1 ANTIGEN AND VARIOUS *O* ANTIGENS TESTED FOR SIALIC ACID, BACTERIOCINE AND HÆMOLYSIN

Organism	Substance tested		
	Sialic acid	Bacteriocine	Hæmolysin
E. coli O1 : *K*1 : *HNM*	+	+	−
E. coli O2 : *K*1 : *HNM*	+	+	−
E. coli O7 : *K*1 : *HNM*	+	+	−
E. coli O16 : *K*1 : *HNM*	+	−	−
E. coli O25 : *K*1 : *HNM*	+	−	−

Negative tests for sialic acid were obtained on the supernates isolated from several different species of heat-treated bacteria. These included 5 *Salmonella*, 7 *Shigella*, 1 *Pneumococcus* (Type 1), 3 *Megatherium* and 2 *Cereus* strains. A strain of *Citrobacter freundii* examined showed strong positive tests for sialic acid. The amount of sialic acid released by heating these cells was equivalent to that obtained from similarly treated *Escherichia coli* strains containing the *K*1 antigen. However, no serological relationship was found by cross agglutination tests between the *Citrobacter freundii* strain and the *Escherichia coli* strains containing the *K*1 antigen.

Therefore, the distribution of sialic acid among *Escherichia coli* strains containing *K* antigens is not widespread. Only 2 of the 19 strains tested indicate that sialic acid appears to form part of the chemical composition of the organism. Of the 77 known serologically different *K* antigens[4] associated with *Escherichia coli* bacteria, some 25 per cent were examined in this study. The richest source of sialic acid occurs in *Escherichia coli* strains which contain the *K*1 antigen. The existence of sialic acid in *Escherichia coli* strains is unrelated to the presence of bacteriocine or hæmolysin. Sialic acid was detected in only one other species of bacteria, namely, a *Citrobacter freundii* strain (*Escherichia coli* 5396/38).

This work has been supported by a grant from the U.S. Public Health Service.

I am indebted to Dr. W. H. Ewing of the Communicable Disease Center, Chamblee, Georgia, for the *Escherichia coli* strains and for the serological classification of *Escherichia coli K*235*L*+*OC*+.

Urinary Excretion of β-Amino-*iso*butyric Acid in Eskimo and Indian Populations of Alaska

VARIOUS studies have shown that the differential urinary excretion of β-amino-*iso*butyric acid is under genetic control[1-4]. Family data indicate that a single major gene pair is responsible for most of the variation in differential excretion of β-amino-*iso*butyric acid, with high excretors being homozygous for a single recessive gene and low excretors either heterozygous or homozygous for the dominant allele. Further investigations have demonstrated marked variation in the frequency of high and low excretors in different races and have indicated the value of this character in genetical-anthropological work[5,6].

β-Amino-*iso*butyric acid appears to be derived from the breakdown of thymine via dihydrothymine and ureido*iso*butyric acid[7]. There is evidence that the differences in excretion-level may be due to differential metabolism of β-amino-*iso*butyric acid by low and high excretors[8].

In view of these considerations, it appeared possible that a comparative study of urinary excretion-rates of β-amino-*iso*butyric acid of Eskimo and Indian populations in Alaska might shed further light on the genetic relationship of these groups and on the selec-

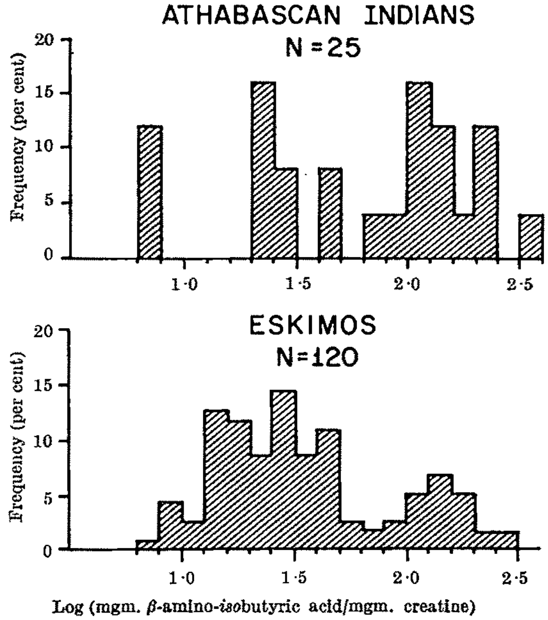

Fig. 1. Frequency distributions of urinary excretion-rates of β-amino-*iso*butyric acid of Athabascan Indians and Eskimos. *N*, number of subjects

tive forces which maintain this polymorphism in the population.

The populations studied were Eskimos from Barrow and Wainwright on the north coast of Alaska and Athabascan (Na-Dene)-speaking Indians from Fort Yukon, Beaver and Arctic Village. Further details of the population structure, which can be taken as randomly selected and nearly all pure-blooded (as indicated by census data), will be given elsewhere[9]. Urine specimens were collected in the field, thymol added as a preservative, and the samples kept at approximately 4° C. for 3–7 days until ready for shipment to the laboratory in Seattle. Determinations of β-amino-*iso*butyric acid were carried out by high-voltage electrophoresis on paper[10], and creatinine was determined by the alkaline-picrate method.

In Fig. 1, the frequency distributions of excretion of β-amino-*iso*butyric acid for the Athabascan Indian and Eskimo populations are presented. The frequencies are bimodally distinguished with the anti-mode at 1·85. Taking the anti-mode as the dividing point between low and high excretors, the frequencies of these classes can now be estimated, and the results, along with comparative values from other populations, are presented in Table 1.

The Alaskan Athabascan and Apache Indian populations show similar high frequencies for excretion of β-amino-*iso*butyric acid, whereas the Whites show a very low rate of excretion. The low rate of excretion for Whites has been well documented in other studies[1,2]. The incidence of high excretion of β-amino-*iso*butyric acid for North American Indians is given further support by some unpublished results of Kraus and Gartler on excretion of β-amino-*iso*butyric acid in the Papago and Pima Indians of Arizona, where values of more than 40 per cent high excretors were found. The excretion-rate of the Eskimo population is intermediate between the Indians and Whites, and differs significantly ($P < 0·01$) from that for the Alaskan Athabascans. The results then argue against any close genetic relationship of the Athabascan Indians and Alaskan Eskimos.

Table 1. Frequency of High Excretors in Various Populations

Population	Sample size	Percentage of high excretors
Alaskan Athabascan Indian	25	56·0
Apache Indian (ref. 4)	110	59·2
Alaskan Eskimo	120	23·3
New York Whites (ref. 3)	218	10·2

There is good evidence for a language affinity between the Apaches on one hand and the northern Athabascan-speaking people on the other[11], and some anthropologists have concluded that the Apache among others represent the southward migrated people from northern tribes[12]. Although the small numbers sampled preclude exact comparisons, the present results are consistent with such a relationship. Furthermore, if the similarity is borne out in more extensive studies, it would appear that there has been little change in the incidence of high excretors in two populations which are thought to have separated from each other 400–600 years ago[13].

It would be of interest to compare the Athabascan and Eskimo values with comparable results from various Oriental populations. However, at present only scanty and not strictly comparable results are available for some Chinese and Japanese groups[5,6]. The results show definitely higher excretion-rates of β-amino-*iso*butyric acid as compared with Whites, but are not sufficient to allow any conclusions regarding the origin of the Athabascan or Eskimo groups.

Collections of specimens in Alaska were facilitated by many individuals and agencies to whom we are indebted; in particular, Col. H. F. Currie, C. Murray and F. Milan of the Arctic Aeromedical Laboratory, Ladd Field; M. C. Brewer of the Arctic Research Laboratory, Barrow; Dr. Burns Jones of the Hudson Stuck Memorial Clinic, Fort Yukon; Drs. C. Dotter and C. Hopkins of the University of Oregon Medical School.

Effect of D-Sorbitol on the Absorption of Orally Administered Vitamin B_{12}

CHOW *et al.*[1] reported that a multiple component lipotropic elixir could increase the absorption of orally administered vitamin B_{12} by healthy subjects. It was afterwards claimed[2] that D-sorbitol was the substance in the elixir which possessed this quality, and radioactive studies in rats by Greenberg and his colleagues[3] supported these results. Morgan and Yudkin[4] produced experimental evidence suggesting that sorbitol could render rats independent of dietary sources of vitamins of the B group.

In view of these findings we have studied serial vitamin B_{12} values of the serum of twelve healthy subjects, who, for periods of 2 weeks or 3 months, took daily oral doses of vitamin B_{12} in water or in the form of a simple syrup, with or without D-sorbitol.

Serum vitamin B_{12} was estimated by the *Euglena gracilis* technique[5]. Each serum was tested three times. On one occasion all sera from each subject were assayed simultaneously. Methods of collection, storage and assay of sera were kept standard throughout. Normal range of serum vitamin B_{12} concentrations has been found[6] to be 130–750 μμgm. per ml. Unless stated otherwise, the daily dose of vitamin B_{12} or vitamin B_{12} and sorbitol was taken before breakfast.

Results to be reported elsewhere[6] show that there may be a physiological variation in the level of serum vitamin B_{12} in normal individuals taking a mixed diet. This was found to be up to 120 μμgm. per ml., and Chow *et al.*[7] have observed differences of even up to 216 μμgm. per ml. when repeating tests on normal subjects over 6–8 months.

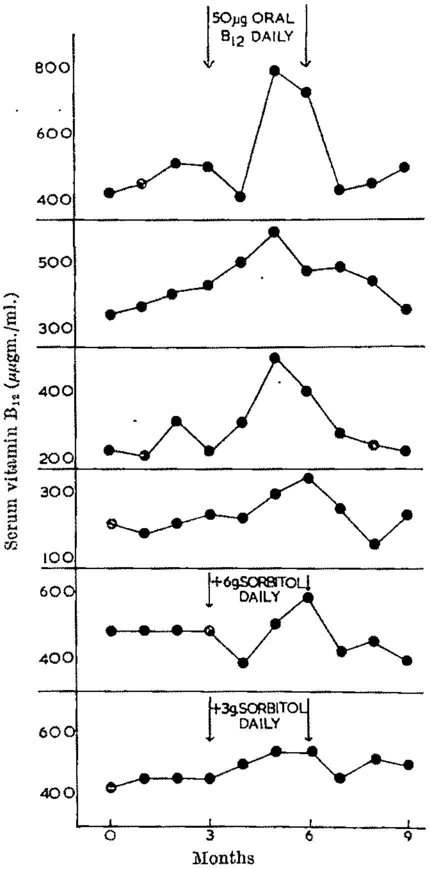

Fig. 1. Serum vitamin B_{12} values of six healthy subjects over a period of 9 months. Oral vitamin B_{12}, with or without additional sorbitol, was taken during the period indicated

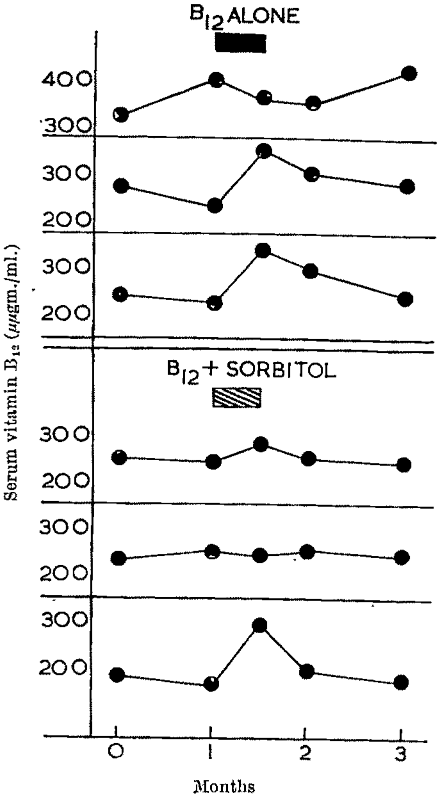

Fig. 2. Serum vitamin B_{12} values of six healthy subjects who received 25 μgm. vitamin B_{12} daily individual oral doses for 2 weeks, three with and three without the addition of 12 gm. sorbitol

As is shown in Fig. 1, two subjects taking either 6 or 3 gm. D-sorbitol daily with 50 μgm. vitamin B_{12} orally for 3 months showed no further increase in serum vitamin B_{12} level when compared with four individuals receiving 50 μgm. vitamin B_{12} in simple syrup.

Likewise, three subjects taking 25 μgm. vitamin B_{12} in water orally daily together with 12 gm. D-sorbitol in three divided doses for two weeks also showed no significant difference from the values obtained in three subjects taking the same dose schedule of vitamin B_{12} alone in water (Fig. 2).

12 geriatric patients without anæmia were given 50 μgm. vitamin B_{12} orally in syrup daily without D-sorbitol for four weeks. The mean serum vitamin B_{12} value of this group before the trial was 240 μμgm. per ml. (range 180–340). At the end of the four-week trial, all values had risen, giving a mean of 370 μμgm. per ml. (range 220–600). In a further group of six old people with a mean serum vitamin B_{12} level of 235 μμgm. per ml. (range 100–390) daily oral dosage of 50 μgm. vitamin B_{12} together with 6 gm. D-sorbitol for four weeks resulted in an increase to a mean serum vitamin B_{12} value of 340 μμgm. per ml. (range 190–540) at the end of the trial. These results, while showing that a rise in serum vitamin B_{12} concentration following such daily dosage can occur, give no support to the view that sorbitol, in the dosage given, increases absorption of vitamin B_{12} from the alimentary tract. Herbert[8] also found sorbitol to have no such effect in cases of pernicious anæmia.

We are grateful to those volunteers who co-operated in taking vitamin B_{12} orally in these studies.

Activation of Thionophosphates by Liver Microsomes

MANY organophosphorus insecticides are poor inhibitors of cholinesterase, but are converted to potent inhibitors ('activated') by certain mammalian and insect tissues. The activation by liver slices was first shown by Gardiner and Kilby[1] for schradan (a phosphoroamidate), and by Diggle and Gage[2] for parathion (a phosphorothionate). Davison[3] showed that both these activations could be effected by the combined soluble and microsomal fraction of liver, if magnesium, nicotinamide and diphosphopyridine nucleotide were provided. I have shown that the soluble fraction could be replaced by reduced diphosphopyridine nucleotide for activation of schradan[4] and malathion[5]. In the present work, a slightly different technique was used for demonstrating activation of phosphorothionate by liver microsomes with reduced diphosphopyridine nucleotide.

Once-washed microsomes were prepared as previously described[4] from a given volume of 10 per cent fresh mouse liver, and resuspended in the original volume of 0·9 per cent sodium chloride. To 0·5 ml. of this preparation was added 2×10^{-5} *M* organophosphate, 0·018 *M* magnesium, 0·01 *M* nicotinamide, and 1 mgm. pyridine nucleotide (usually reduced diphosphopyridine nucleotide), giving a total volume of 2·5 ml. The mixture was shaken for 30 min. at room temperature in a 50-ml. beaker (it was essential to expose a large surface area). Samples were then diluted 2, 20 and 200 times, and duplicate 1-ml. portions were added to 1·5 ml. of 7·5 times diluted human plasma, and incubated at 37° C. for 30 min. Acetyl choline bromide (0·2 ml. of 5 per cent) and 7·3 ml. of water were added and the cholinesterase activity determined by titrating to constant *p*H, using a micrometer syringe and a *p*H meter, with the sample at 37° C. being stirred by carbon dioxide-free air at 37° C.

In order to obtain a standard preparation, mouse microsomes were at first prepared in bulk (that is, from 20 gm. of liver), rapidly frozen in units sufficient for one day's work, and stored in the refrigerator. This treatment had previously been shown[4] to maintain activity, whereas under any other conditions activity disappeared in 24 hr. However, these frozen preparations deteriorated slowly, being inactive after eight days. Microsomes were therefore prepared fresh each day for the experiments reported here.

Table 1

Trivial name	Chemical name	Per cent cholinesterase inhibition: With microsomes	Per cent cholinesterase inhibition: Without microsomes
1. Co-ral	O,O-Diethyl O-(3-chloro-4-methyl-7-coumarinyl) phosphorothionate	89	10
2. Malathion	O,O-Dimethyl S-(1,2-dicarbethoxyethyl) phosphorodithioate	33	22
3. Guthion	O,O-Dimethyl S-(4-oxo-1,2,3-benzo-triaxinyl-3-methyl) phosphorodithioate	42	0
4. Diazinon	O,O-Diethyl O-(2-*iso*propyl-6-methyl-4-pyrimidyl) phosphorothionate	72	5
5. Potasan	O,O-Diethyl O-(4-methyl-umbelliferyl) phosphorothionate	85	26
6. 'Dimethoate'	O,O-Dimethyl S-(N-methylcarbamoylmethyl) phosphorodithioate	0	0
7. Trolene	O,O-Dimethyl O-2,4,5-trichlorophenyl phosphorothionate	43	0
8. EPN	O-Ethyl O-*p*-nitrophenyl phenylphosphorothionate	46	2
9. 'Tetram'	O,O-Diethyl S-(β-diethylamino) ethyl phosphorothiolate	50	47
10.	O,O-Diethyl S-(β-diethylamino) ethyl phosphorodithioate	93	18
11. Parathion	O,O-Diethyl O-*p*-nitrophenyl phosphorothionate	60	11
12.	Tetraethyl phosphorodiamidic anhydride	15	9

Pyridine nucleotide was reduced diphosphopyridine nucleotide. Figures are for organophosphates at 4×10^{-7} *M* (except 'Tetram', 4×10^{-9} *M*) at stage of incubation with cholinesterase. A different microsome preparation was used for each compound.

The results (Table 1) show activation of all compounds except 'Dimethoate' and 'Tetram'. The latter was included to test the possibility that dialkylaminophosphates might be activated: it appears that they are not. Microsomes can hydrolyse 'Acethion' (O,O-diethyl S-carboethoxymethyl phosphorodithioate) at the carboxyester group, and as a consequence do not show activation of 'Acethion'[6]. This may hold for 'Dimethoate' and (to a lesser extent) for malathion. The poor activation of tetraethyl phosphorodiamidic anhydride, compared with the strong activation of its methyl analogue, schradan[4], demonstrates that this system, which is so non-specific with phosphorothionates, is highly specific for certain phosphoroamidates.

The pyridine nucleotide requirement was also studied (Table 2). As in the activation of schradan[4], the reduced nucleotide is preferred; yet even the unreduced diphosphopyridine nucleotide shows clear activity; and reduced triphosphopyridine nucleotide is at least as good as reduced diphosphopyridine nucleotide.

This work shows that out of the ten thionophosphates studied (that is, the compounds of Table 1 except for Nos. 10 and 12), nine were activated by a preparation of microsomes and reduced diphosphopyridine nucleotide.

This communication has been approved for publication by the Director of the Wisconsin Agricultural

Table 2

Pyridine nucleotide	Per cent cholinesterase inhibition: Parathion 4×10^{-7}	Per cent cholinesterase inhibition: Parathion 4×10^{-8}
Nil	11	6
Diphosphopyridine nucleotide	60	9
Reduced diphosphopyridine nucleotide	100	39
Triphosphopyridine nucleotide	39	28
Reduced triphosphopyridine nucleotide	100	56

Systems contain 1 mgm. per flask of pyridine nucleotide indicated. Concentrations given are for parathion or products at stage of incubation with cholinesterase. All results are from the same microsome preparation.

Experiment Station. The experiments were performed by Mr. V. K. Patel, and the study was supported in part by funds from the Wisconsin Alumni Research Foundation.

BIOLOGY

A Sex Difference in Radioactivity of *Artemia* cultured in Sea Water containing Phosphorus-32

PHOSPHORUS as a constituent of energy storage-transfer systems and as a structural component of nucleic acid is essential to life. As such it is not surprising that its radioactive form has proved to be the isotope of greatest biological importance in the disposal of liquid wastes from atomic energy installations[1]. The present report concerns a phase of a long-term investigation on the genetic effects of radiation on populations of marine animals.

During the summer of 1958, phosphorus-32 was added in known concentration to sea water containing adult brine shrimps, *Artemia salina*. Afterwards, Geiger–Müller counts were made of individual adults and of samples of the sea water. Over a significant period of time, females were more radioactive than males.

An American diploid amphigonic strain of *Artemia* has been maintained in jar cultures for 4 years. Similar cylindrical jars, 27 cm. × 15·6 cm., were used for the present experiment. Thirty pairs of adults were placed in 3 litres of sea water. Then 30 μc. of phosphorus-32 was added. The chemical form was hydrogen phosphate in dilute hydrochloric acid solution. Adults were removed periodically, washed thoroughly in sea water, killed and dried, one per planchette. At the same time, a sea-water sample equivalent in mass to an *Artemia* was also dried on a planchette. A measure of the radioactivity was then obtained by counts taken with an El-Tronics, Inc. Scintillation Scaler, Model *LS*6455, using a shielded manual sample changer, Tracer Lab., Inc. Model *SC9E*.

In the first experiment, the relative radioactivity of sea water and of a single male and female was assessed nearly every day for a 20-day period. The results demonstrated early achievement of a high peak in female radioactivity and a levelling off for both sexes at about the tenth or eleventh day, by which time uncentrifuged sea water showed little radioactivity above background.

A second experiment was then set up to provide at least two animals of each sex to be counted each day for 15 successive days. Results are summarized in Fig. 1. The radioactivity of females was consistently above that of males until nearly two weeks had elapsed. Although they were already more radioactive than centrifuged sea water after one day, *Artemia* did not surpass the radioactivity of uncentrifuged sea water until 3 or 4 days. This is taken as evidence of the transfer of radiophosphorus through the food-chain. Uncentrifuged water contained *Chlorella*, bacteria and yeast cells. The latter are added to the culture as a diet supplement in amounts of 3 drops of dilute suspension per day.

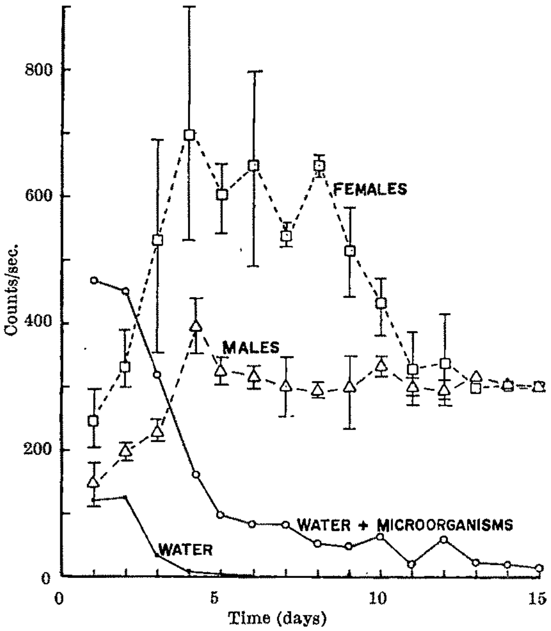

Fig. 1. The relative radioactivity of *Artemia* and the sea water in which they were maintained after a single addition of phosphorus-32 on day zero. The limits shown are the extreme low and high values for each day

In order to determine what happens during the first 24 hr., a third experiment was set up in which individuals were killed every hour for the determination of radioactivity. A sharp threshold was found between 9 and 10 hr. Before this, all animals were low in radioactivity; after this they were highly radioactive. This corroborates that radiophosphorus association with *Artemia* is through ingestion as food rather than through adsorption or absorption. The period of time between addition to the culture and appreciable radioactivity of brine shrimp may reflect time required for biosynthetic incorporation by the micro-organisms.

A peak and decline of female radioactivity (Fig. 1) may be explained by loss of phosphorus-32 through incorporation into offspring. At least one F_1 group was produced by the adults during the period of Fig. 1. Furthermore, on the basis of a brood every 4½ days[2], females considered after the ninth day could already have given birth to two broods, thereby dispersing radiophosphorus into 30–140 offspring. Since the *Artemia* life-span averages 4 months[2] while the half-life of phosphorus-32 is only 14·3 days, detection of a re-occurrence of the sex difference due to re-cycling of phosphorus-32 seems unlikely.

In the wasp *Habrobracon*, Grosch and Sullivan[3] showed that 60 per cent of a radiophosphorus meal fed to females was deposited in the eggs. Also, measured in terms of dominant lethals, the same meal is much less potent if fed to males[4]. In houseflies, females of two strains became more radioactive than males[5]: in two species of *Drosophila*[6] turnover of phosphorus-32 differs between males and females, and female mosquitoes become twice as radioactive as males[7]. Since exceptionally high turnover of phosphorus associated with oviposition also characterizes laying hens[8], the phenomenon is not limited to the phylum Arthropoda.

In radio-ecological studies it has been customary to consider season, development and age for members of various species[9]. Present results suggest that sex is also a matter of importance. The degree of induced sterility and zygotic dominant lethality now under study is otherwise unexplained.

A Correlation between Iodine Permeability and the Gram Characteristic of Cells

Kaplan and Kaplan[1] demonstrated that the addition of iodine to the alcohol used as a decolorizer in the Gram procedure resulted in retardation of the rate of decolorization. If the concentration of iodine was sufficiently high, no decolorization occurred. They also found that much higher concentrations of iodine in the alcohol were necessary to prevent the decolorization of Gram-negative bacteria than for Gram-positive bacteria. In their opinion these results indicated that differences in permeability to iodine in alcoholic solution contributed to the mechanism of Gram differentiation. In confirmation of the above work, Mittwer, Bartholomew and Kallman[2] demonstrated that iodine in alcoholic solution stained Gram-negative cells much faster than Gram-positive cells. No such difference was demonstrable for iodine in aqueous solutions. The nature of the proof presented by the above workers, however, lacked accurate and objective results, and could not be considered as conclusive. When the methods of filter paper chromatography are applied to this problem, accurate and objective results can be obtained easily.

The chromatographic apparatus used consisted of 8 in. × 1¼ in. glass test-tubes with cork stoppers. 8 ml. of solvent were placed in the bottom of the tubes. A cut was made in the bottom of the cork with a knife. The top of a filter paper strip (7¼ in. × ¾ in., Whatman No. 1) was inserted into the cut. The cork and filter paper assembly were then inserted into the test-tube. This resulted in the bottom ¼ in. of the filter paper being immersed in the solvent.

Cell suspensions were prepared by harvesting the cells from a 48-hr. Petri-dish culture in 5 ml. of sterile water. Nutrient agar was used for bacterial cells, and wort agar for yeast cells. The suspension was transferred to a test-tube and centrifuged. Following centrifugation the supernatant was decanted, and 3 ml. of Gram's iodine solution added. The cells were resuspended in the iodine solution for 5–10 min., and then recentrifuged. The supernatant was drained off. The cell paste remaining was then used in the experiments. Approximately 0·005 ml. of this paste was deposited in a thin line across the width of the filter paper, at a distance of about 1 in. from the bottom. Sahli pipettes (0·02 ml. volume) were found useful for this purpose. The preparation was allowed to dry for about 1 hr. Occasionally, when the cell paste was too thick, the cells would separate from the filter paper during the drying period. This could be prevented by thinning the cell paste in the test-tube by adding one drop of iodine solution and afterwards washing the free iodine from the filter paper – cell preparation by the following method. After drying, the lower end of the filter paper carrying the cells could be immersed in 96 per cent alcohol in a series of 3–5 Coplin jars for 1 min. in each jar. This effectively removed free iodine from the filter paper but left sufficient in the cells for the purposes of the experiments. After drying, the filter paper strips were then placed in the chromatographic apparatus containing 8 ml. of solvent. After 1 hr. the strips were removed, dried, immersed in 0·5 per cent aqueous starch solution, dried with blotting paper, then air dried. The distribution of iodine was indicated by the blue colour.

The Gram-positive organisms used were *Saccharomyces cerevisiae*, *Staphylococcus aureus* and *Sarcina lutea*. The Gram-negative organisms used were *Escherichia coli*, *Proteus vulgaris* and *Pseudomonas fluorescens*. Fig. 1 shows the results for two Gram-positive (*A*,*B*) and two Gram-negative (*C*,*D*) organisms. The cells treated with iodine were exposed to 96 per cent alcohol as a solvent in the chromatographic apparatus. The difference in loss of iodine between Gram-positive and Gram-negative organisms could be seen visually before the strips were immersed in the starch solution. The starch solution was used in an attempt to aid photographic representation of the results obtained. In some instances no detectable iodine left the Gram-positive cells, as compared with a plentiful and continuous loss of iodine from Gram-negative cells. In other instances the loss of iodine from the Gram-positive cells was sufficient to give a very faint blue colour with starch, as com-

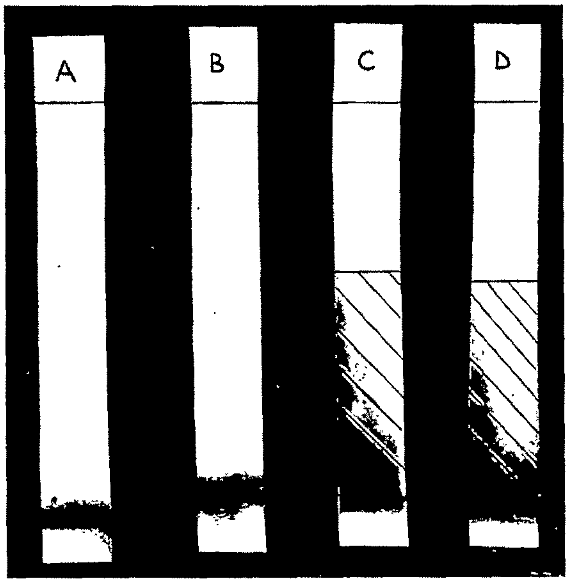

Fig. 1. Cells treated with iodine, then exposed to 96 per cent alcohol as the solvent in a chromatographic apparatus. *A*, *Saccharomyces cerevisiae* ; *B*, *Staphylococcus aureus* ; *C*, *Escherichia coli* ; *D*, *Proteus vulgaris*. A 0·5 per cent aqueous starch solution was used to aid in the photographic demonstration of iodine distribution. During exposure to aqueous starch the thick blue line at the base of the strips appeared due to iodine diffusion out of the cells (strips *A*, *B*). The top line represents the height reached by the solvent, the cross-hatching the area of deep blue colour

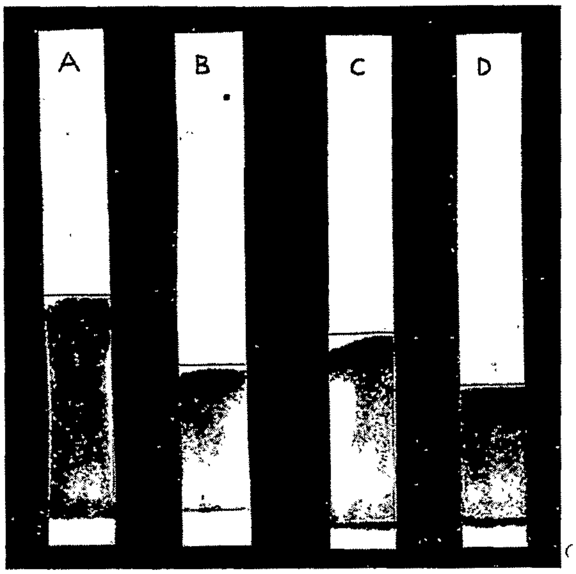

Fig. 2. Same as Fig. 1 except that filter paper strips were exposed to 0·5 per cent aqueous starch solution as the solvent in the chromatographic apparatus

pared with a very deep blue colour given when Gram-negative cells were used. No exceptions to these differences were found during repeated testing of three species of Gram-positive organisms and three species of Gram-negative organisms. Fig. 2 shows a similar series of filter paper strips, except that aqueous starch solution was used as a solvent in the chromatographic apparatus. It can be seen that under aqueous conditions the iodine left both Gram-positive and Gram-negative cells at a very rapid rate. This difference between alcohol and aqueous solvents and their effect on loss of iodine from bacterial cells confirms the observations of Mittwer, Bartholomew and Kallman[2]. If filter paper strips with organisms were first placed in the chromatographic apparatus for 1 hr. with 96 per cent alcohol as a solvent (or washed in alcohol by the procedure given above), then dried and again placed in the apparatus with aqueous starch solution as a solvent, results were obtained identical with those shown in Fig. 2. This demonstrated that exposure to alcohol under these conditions left considerable residual iodine in the cells. The differences shown in Fig. 1, therefore, represented differences in the rate of loss of iodine.

The above results show clearly the difference between Gram-positive and Gram-negative organisms in the rate of iodine loss when alcohol is used as a solvent. We are now trying to obtain better quantitative results by using radioactive iodine. It is yet to be demonstrated whether the above differences are responsible for Gram differentiation or merely correlated with it.

Dependence of the Heat Resistance of Bacterial Endospores on their Dipicolinic Acid Content

IT is generally accepted that mature spores from aerobic or anaerobic bacteria contain large quantities (5–15 per cent of the dry weight) of dipicolinic acid, whereas it is absent in the non-resistant vegetative cells[1,2]. Biosynthesis of dipicolinic acid is usually considered to be indicative of the formation of heat-resistant spores. In *Clostridium roseum*[3] sporulation involves the development first of a refractile spore-like body, which is followed by the synthesis of dipicolinic acid, and later of a heat-resistant spore. In the aerobic bacteria, however, a close correlation between these three processes makes difficult the isolation of the first stage in sporulation.

In collaboration with Dr. George Cohen, we have been studying the route of the biosynthesis of dipicolinic acid in *Bacillus cereus* var. *terminalis* by isotopic competition experiments. During the course of these studies, it was observed that the presence of phenylalanine during sporulation reduced the level of dipicolinic acid formed. These findings have led us to examine further the specificity of this suppression and the relationship between the dipicolinic acid content, viability and heat resistance of the free, mature spore.

Spores of *B. cereus* var. *terminalis* were produced in 100-ml. flasks containing *G* medium[4] supplemented with various amino-acids. The flasks were shaken aerobically at 30° C. until lysis of the vegetative cells had proceeded to the point where the culture contained more than 90 per cent free spores. The spores were first separated from the vegetative debris by centrifugation at 1,500 r.p.m. for 1 hr. in a solution of higher specific gravity (40 per cent sucrose). The spores were then further cleaned as previously described[4]. The washed spores were lyophilized and their dipicolinic acid content determined on a 15–20 mgm. sample by the method of Janssen *et al.*[5]. To measure heat resistance, an aqueous suspension (1 mgm. spores/ml.) was heated to 80° C. and aliquots removed at intervals for measurement of viability.

The results in Table 1 show that the dipicolinic acid content of spores is lowered from 74 to less than

* Abbreviations: *YE*, yeast extract; *P*, pantothenic acid; *T*, thiamine; *F*, folic acid; *R*, riboflavin; *B*, biotin.

The following additions were employed: *YE*, mgm./100 ml. *G* medium; vitamins, μgm./100 ml. *G* medium; amino-acids were added at 200 mgm./100 ml. *G* medium.

† Calculated from equation $K = \frac{1}{t_2 - t_1} \log \frac{N_1}{N_2}$, where t is time of exposure at 80° C. in min.

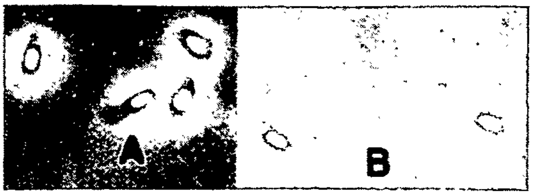

Fig. 1. Spores of *Bacillus cereus* var. *terminalis*, produced in the presence (*A*) or absence (*B*) of 1 mgm./ml. DL-phenylalanine (× 1,000)

0·2 μgm./mgm. spores by reducing the level of yeast extract in the sporulation medium. The dipicolinic acid content is raised by the addition of vitamins, suppressed by the addition of DL- or L-phenylalanine and relatively unaffected by the presence of various other amino-acids. The inhibition of the synthesis of dipicolinic acid by phenylalanine was not reversed by increasing the level of yeast extract.

With the possible exception of spores produced in medium containing 0·2 mgm. yeast extract/100 ml. medium without added vitamins, variation in the dipicolinic acid content is not reflected in the appearance of the spore. As shown in Fig. 1, spores grown in L-phenylalanine are indistinguishable from spores grown in *G* medium. In all cases the spores were refractile and impermeable to methylene blue. Germination and resporulation in *G* medium of spores low in dipicolinic acid yielded spores with a normal dipicolinic acid content.

Fig. 2 shows the relation between dipicolinic acid content, viability and the rate of heat inactivation of the spores in Table 1. Above 1·2 per cent dipicolinic acid, viability is independent of the dipicolinic acid content; however, as the level of dipicolinic acid is reduced below 1·2 per cent, the proportion of non-viable, spore-like bodies increases. The rate of heat inactivation shows a biphasic dependence on dipicolinic acid content. It thus appears that dipicolinic acid protects at least two sites of the spore against heat inactivation.

Although the ubiquitous presence of dipicolinic acid in mature bacterial spores has led to some speculation on its role in regulating the metabolic activity of the spore[6], little information is available on the function of the acid in heat resistance. Clearly, further information on the state of dipicolinic acid in mature spores and correlations between the contents of that acid and divalent metals and heat resistance is necessary to clarify the function of the acid. Although the present experiments have demonstrated a dependence of heat resistance on the acid content, attempts to protect enzymes in spore extracts against heat inactivation with dipicolinic acid have thus far had negative results[2].

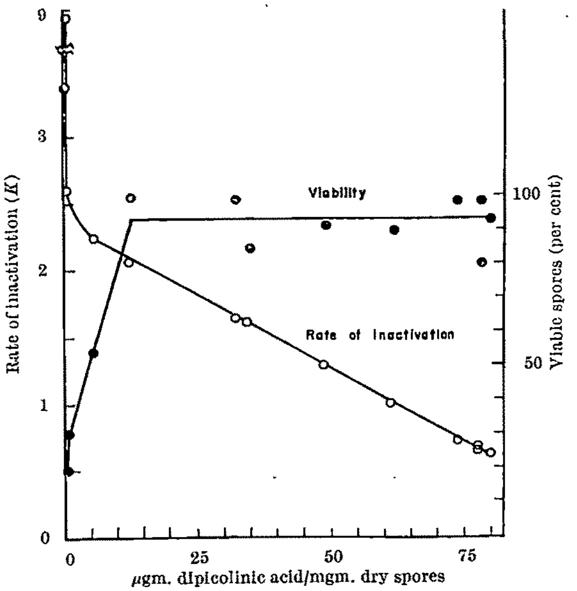

Fig. 2. Effect of the dipicolinic acid content on the viability and heat resistance of bacterial spores

Work is in progress to examine the physiology of spores with low dipicolinic acid contents.

Genetic Independence of Four Mutants in the Syrian Hamster

GENETIC tests have been completed for possible linkage between the four mutant alleles, ruby-eye (*ru*) and cream[1] (*e*), acromelanic albinism[2] (c^d) and piebald spotting[3] (*s*), of the hamster *Mesocricetus auratus*. Each of the ten possible combinations with four genes, and with the sex-differentiating segment of the *Y* chromosome treated as a dominant gene, has been studied.

Only one of the ten combinations yielded a disturbed genic segregation which could possibly be interpretated as linkage. The two mutants concerned are *ru* and *s*, and the disturbed segregation, which is a repulsion F_2, is as follows:

RuS	*ruS*	*Rus*	*rus*	Associative χ^2
684	172	87	8	7·59

However, the two genes are known individually to confer a semi-inviability, and the observed figures could also be interpreted as due to an inviability interaction resulting in excessive mortality of the *rus* class. An indication that such an effect could be operating is given by an analysis of variance of 21-day weight of the F_2 generation, which revealed significant differences between the four classes. Taking the normal class as standard, the percentage weights of the following three are 83, 77 and 45. If the respective weight reductions for the presence of *ru* and *s* are independent, the combined reduction would be expected to be of the order of 64, rather than 45, per cent.

The two interpretations may be effectively distinguished by the joint consideration of two F_2's, one in repulsion and the second in coupling phase. The production of the second F_2 necessitates breeding from *ruruss* animals, and this is complicated by the

Table 1

Phase	*RuS*	*ruS*	*Rus*	*rus*	Associative χ^2
Coupling	153	37	24	1	3·64
Repulsion	150	40	23	1	3·92

impaired fertility of *ruru* males[1,4] and small size and weakened maternal instincts of *ruruss* females. No *ruruss* males have been found to be fertile; but, by persevering with *ruruss* females, suitable F_1 young were reared, which produced the F_2 of Table 1 (first row).

The number (215) constituting the coupling F_2 is too few to balance adequately the much larger original repulsion F_2, so the first 55 litters from the latter, comprising 214 young, were extracted (Table 1, second row). The two distributions agree closely, and it may be inferred, therefore, that the disturbed segregation of *ru* and *s* is not due to linkage but to an inviability interaction. A maximum likelihood analysis for departure from random assortment is presented below. The total score (3·14) represents a negligible deviation.

Phase	Score	Information	χ^2
Coupling	46·506	576·369	3·70
Repulsion	−49·650	628·931	3·92
	−3·144	1,205·300	0·01

A summary of results for the remaining nine combinations is presented by Table 2. The *ru-Y* comparison just attains a significant value of χ^2 but further analysis suggests that this may either represent a small inviability interaction, such that the male *ruru* is less viable than female *ruru*, or be due to a not improbable chance deviation occurring among a number of sub-sets of data.

Table 2

Mutants	Score	Information	χ^2
e-ru	−73·333	3,168·591	1·69
e-s	17·111	1,281·912	0·24
e-c^d	20·889	930·962	0·47
e-Y	−28·000	3,254·208	0·24
ru-c^d	−24·988	938·183	0·66
ru-Y	−113·333	3,331·970	3·85
s-c^d	− 12·813	138·012	1·19
s-Y	10·667	1,028·423	0·11
c^d-Y	62·000	2,793·333	1·38

No evidence for linkage is apparent from these results. The Syrian hamster has 22 chromosomes, and an idea of the probability of finding at least one linkage with 4 mutant genes among 21 autosomes may be computed by Green's method[5]. The probability is merely 26 per cent. The number of mutants required for the probability of linkage to exceed that of no-linkage is 6, but the probability (54 per cent) is not high. Of the residual probabilities, only that for a single linkage is appreciable (43 per cent). It may be concluded that the discovery of many more mutant genes is necessary before the chance of linkage detection in the hamster tends to approach certainty.

Control of Diapause by an 'Internal Clock' in *Anthrenus verbasci* (L.) (Col., Dermestidae)

THE life-history of this carpet beetle under outdoor conditions in southern England is as follows. Adults emerge in June and July and may be found on many species of creamy-white flowers, notably cultivated *Spiraea* spp. and *Heracleum sphondylium* L. (hogweed). One of the main oviposition sites is dry birds' nest material found in the attics of buildings. Eggs hatch in about five weeks, but larvæ may require two years for complete development. Pupation occurs in early May, and lasts about a month; after a further week of inactivity the active adults emerge. When mating occurs immediately, eggs are laid from about one week onwards for at least a month. Adults die about the end of July. Experiments on the development of larvæ under outdoor conditions showed a clear annual rhythm of activity, namely, a rapid rate of moulting during the summer (May–August) and rest during the winter.

A striking feature of the development of this species, and one which, so far as I can discover, has not previously been demonstrated for an annual rhythm in any animal, is that this cycle of active growth and rest persists when development takes place under constant physical conditions in the laboratory. When larvæ were reared at constant temperatures of 15·0–25·0° C., the frequency distribution of times of pupation was clearly bi-modal (Fig. 1). Larvæ which pupated in the first group had only one period of diapause and their development was completed in a single one-year cycle, but those which pupated in the second group had two periods of diapause and followed a two-year cycle. The proportion of individuals taking one or two years to complete development was dependent upon the temperature (Fig. 1).

There was alignment of the active periods of individuals at different temperatures. During the first active period, which followed immediately after emergence from the egg, the increase in size was roughly proportional to the temperature. Consequently, at the end of the first active period larvæ developing at 15·0° C. were only small, while those

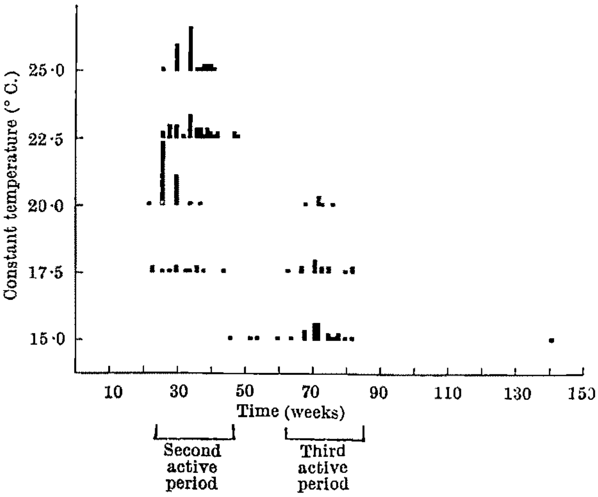

Fig. 1. Frequency of pupation times when larval development has occurred in constant conditions of temperature, humidity and darkness. For each temperature development took place at 30 per cent and 70 per cent relative humidity. A black square represents the time of pupation, to the nearest week, of one individual

at 25·0° C. were fully grown. There followed a period of diapause when little or no development occurred. Next came a second active period, during which the small larvæ moulted and reached the fully grown stage, while the larvæ already fully grown pupated, forming the first-year group of pupæ. This alignment of alternating active and diapause periods, in individuals developing at different temperatures, and therefore at different stages in their development, indicates an internal rhythm of development common to all.

The length of the cycle in this rhythmic development under constant conditions is about forty-one weeks, compared with the annual rhythm of development under outdoor fluctuating conditions. It is considered that the shorter interval is the basic one, and that, when diapause is completed, activity (involving both moulting and pupation) will proceed as soon as the temperature is above the threshold for development. This also furnishes an explanation for the lack of variation in the time of pupation under outdoor conditions (29 individuals varied by less than 4 days at the end of two years development) compared with that under constant conditions (Fig. 1).

Some of the laboratory experiments commenced in August, some in November and some in December. Relative humidity was controlled, and any diurnal or seasonal changes in carbon dioxide concentration were masked. The experiments were carried out in complete darkness except for short exposures of the insects to daylight or to tungsten illumination when they were being examined. Some experiments were started with the progeny of adults from laboratory cultures, others with the progeny of adults from flowers, but these differences did not materially influence the results. All eggs were incubated at 20·0° C., 70 per cent relative humidity, and the experiments set up with newly emerged larvæ.

At 20° C. simple crossings were made between individuals taking two years to develop. The F_1 progeny fell into two groups (one-year and two-year) in approximately the same proportion as in the original population.

A more detailed account is in the press[1].

A New Method for delaying Pupation in *Drosophila melanogaster*

Methods of delaying pupation in *D. melanogaster* are not only of interest in relation to the physiology of metamorphosis but also provide useful tools for developmental-genetical studies. Up to the present, the main method available has been that of Beadle, Tatum and Clancy[1]. They kept larvæ, aged less than 70 hr., on a low food-level provided by 1·5 per cent agar and 0·25 per cent brewer's yeast. According to Bodenstein[2] most of the larvæ starved in this way fail to survive, particularly, of course, those starved from early ages; moreover, the period for which pupation is delayed is highly variable, since in some cases larvæ pupate only one day late whereas in others the delay might be as much as five days.

A method has been found to delay pupation from six to seven days. The experiments were made with wild-type *Or.K.* stock. The eggs were laid over a 2-hr. period on agar medium and left for 20 hr., after which all the larvæ hatched during this period were removed. The remaining eggs were then raised on agar-molasses medium composed of 2 per cent agar, 17 per cent molasses and 1·5 per cent dry yeast. After 70 hr. from egg deposition (48 hr. after hatching), the larvæ were transferred to other vials containing the same food medium mixed with benzamide at concentrations of 2·0–6·0 per cent. In each vial, 12–15 larvæ were raised. Throughout the whole period of experiments, the temperature was kept at 25° C.

Nine days from egg-hatching, that is, five days after the control larvæ had pupated and one day after the flies had emerged from the pupæ, the test vials were examined. As shown in Table 1, at 2·0 per cent benzamide, about 88·8 per cent of the test larvæ have retained their larval characteristics, the remainder having become prepupal. The mortality-rate was insignificant.

Table 1. Effect of Benzamide on 48-hr.-old Larvæ of *D. melanogaster* (observed Nine Days after Hatching)

Conc. (per cent)	No. of test larvæ	Larvæ retarded		Pre-pupæ		Mortality-rate	
		No.	Per cent	No.	Per cent	No.	Per cent
2·0	54	48	88·8	5	9·2	1	2·0
4·0	69	66	95·6	—	—	3	4·4
6·0	69	67	97·1	—	—	2	2·9

At 4·0 and 6·0 per cent benzamide no pupation occurred, and nearly all the test larvæ remained in the food culture as mature third instar. These arrested larvæ were well able to withstand the experimental conditions, mortality-rate being small. When they were transferred to ordinary food, the percentage of recovery was very high. Pupation usually occurred 1–2 days after the transference. In other words, the whole period of delay was 6–7 days, 5 days with the treated food and 1–2 days with the ordinary one.

Table 2. Fate of Retarded Larvæ after Transference to Ordinary Food

Conc. of benzamide (per cent)	No. of transferred larvæ	Recovered larvæ	
		No.	Per cent
2·0	24	23	95·8
4·0	22	21	95·4
6·0	20	18	90·0

I am indebted to Prof. C. H. Waddington for his encouragement throughout the progress of the work.

Collagen in the Perilemma of Insect Nerve

Insect nerves are enclosed in a sheath, the perilemma, made up of concentric layers of anisotropic protein micelles and resembling the connective tissue of vertebrates[1]. There is evidence that each lamina consists of rows of glycoprotein fibrillæ, oriented at right angles in successive layers, the whole embedded in a matrix of neutral mucopolysaccharide[2].

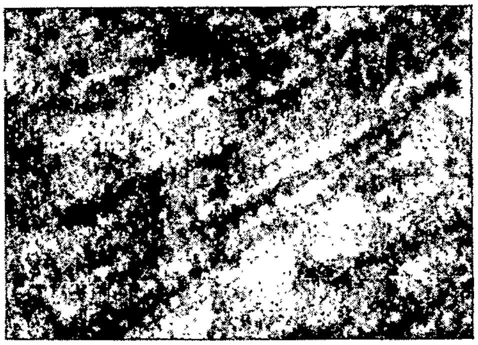

Fig. 1. Tangential section of perilemma of *Rhodnius* nerve. (× 30,000)

There has been some doubt as to whether the fibrous component of the perilemma is a collagen. Collagen is widely distributed in invertebrates[3]. By X-ray diffraction methods (wide-angle pattern), its presence has been established in crab nerve[4] and in subcuticular tissues of Crustacea and Mollusca[5]. By the same means Rudall[5] obtained definite evidence of its presence in small quantities in the ventral nerve cord of large mantids.

In the course of a re-investigation of the histology of the insect nervous system (V. B. W.), sections of the perilemma of the ganglia and large nerves of *Rhodnius prolixus* (Hemiptera) were prepared for the electron microscope (D. S. S.). Transverse sections reveal a series of rather dense fibrillar layers, with looser tissue between in which the fibres are differently oriented. Fig. 1 represents a somewhat thick tangential section showing the feltwork of banded fibres in one of the dense laminæ. Approximate measurements made on thinner sections gave a main periodicity of around 500–600 A. and a minimum diameter of about 150 A. In some fibres there are traces of secondary periodicity. These characters fall within the range of those of collagen in other groups of animals[3].

Chromosome Number of the Potato Root Eelworm, *Heterodera rostochiensis* Wollenweber

Riley and Chapman[1] have recently reported that the diploid chromosome number of the female potato root eelworm is 18. During the course of a comparative study of the cytology of the genus *Heterodera*, I have found from a study of eggs undergoing meiosis that although this number appears to be usual in the potato root eelworm, eggs having 20 and 22 as the diploid number are not uncommon, while occasional eggs with 19, 23 and 24 may also occur. Material was fixed in Carnoy's fluid and stained with 1 per cent orcein in 45 per cent propionic acid using a squash technique. The distribution of chromosome number shown in Fig. 1 is based on 40 eggs from 32 females. In most cases where it has been possible to determine the chromosome number for more than one egg per female the determinations have agreed, but it is not certain whether this is always the case. The chromosomes are approximately 1μ long, so that counts may not be accurate in all cases; nevertheless it is clear that the number of chromosomes varies.

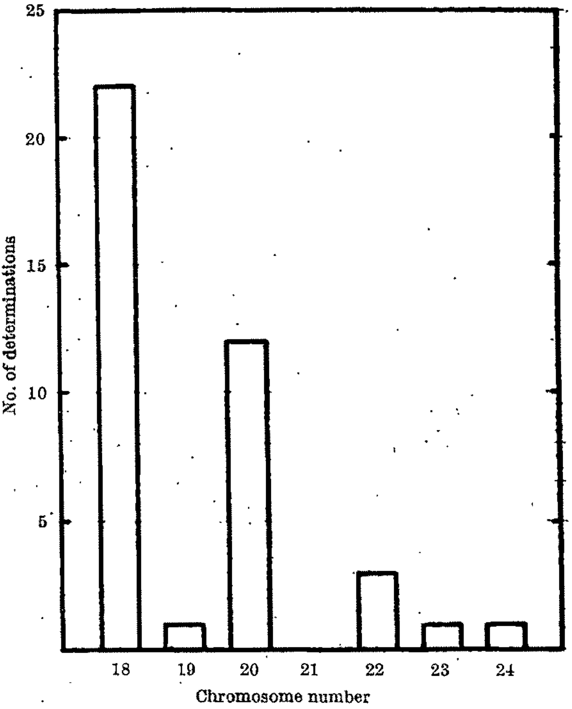

Fig. 1

One fertilized female was also found containing eggs with abnormally high chromosome numbers. 21 eggs were present, six undergoing meiotic division, and of these one had 47 chromosomes clearly arranged in a first anaphase figure, 23 in the upper plate and 24 in the lower. In none of the other five eggs were the chromosomes sufficiently clear to permit an accurate count, but in four of them the unreduced chromosome number was not less than 36, a number which falls outside the range shown in Fig. 1. The egg containing 47 chromosomes was apparently tetraploid; it is not possible, however, to say whether the whole of the parent female was tetraploid or only portions of the reproductive tract. Some years ago, Onions[2] reported from this laboratory the occurrence of four giant larvæ of potato root eelworm in one cyst (female), and suggested that they might be polyploid; their egg shells were also about twice the normal size. In the present case, the sizes of four fixed and stained eggs having abnormally high chromosome numbers fell within the range for comparable eggs of normal chromosome number.

The work is supported by a grant from the Agricultural Research Council, for which I wish to express my thanks.

Singing Pattern of the Common Chaffinch, *Fringilla coelebs* Linn.

In a recent communication[1] describing the results of research carried out at Cambridge on song learning in *F. coelebs gengleri* it is stated that the natural song of this bird has a length of 2–2·5 sec., followed by a silent interval of 10–20 sec. Systematic records of the singing pattern of *F. coelebs* obtained here over a number of years suggest that Cambridge results quoted above may not be fully representative of the native chaffinch population of the British Isles.

The present communication describes the results obtained from detailed records of chaffinch song at Sidmouth covering three breeding seasons—1946, 1953 and 1954. Values of the 'song interval', defined by the time taken to utter the characteristic tri-phrase song once, have already been reported for the season of 1946[2]. The results presented here include new data on the rate of singing obtained in 1953 and 1954 based on a total of 9,435 records of individual birds belonging to the same local population as that used in 1946.

From the combined data, grouped mean values of total singing time, T_s, and total silent period T_q (both expressed in sec. per min.) have been derived for 10-day intervals during the breeding cycle. Additionally, 10-day mean values of the quantity, 100 (T_s/T_q), designated hereafter the 'song ratio', have been computed to provide a useful index of singing activity. Table 1 summarizes the results obtained during the most active period of breeding song for 55 until 125 days from the onset of singing.

Table 1. Seasonal March of Song Activity (*F. coelebs* Linn.)

Days from onset of singing	Song interval (sec.)	Song frequency (per min.)	T_s	T_q	Song ratio (per cent)
55	2·00	6·4	12·8	47·2	27
65	2·05	6·8	14·2	45·8	31
75	2·15	7·1	15·3	44·7	34
85	2·20	6·6	14·5	45·5	32
95	2·20	5·5	12·1	47·9	25
105	2·15	4·8	10·3	49·7	21
115	2·10	4·7	9·9	50·1	20
125	2·00	4·7	9·4	50·6	19

Both duration of song and rate of singing are seen to vary in response to the biological stimulus of the breeding cycle. The former exhibits a flat maximum at 85–95 days from onset of singing, while the latter passes through a more pronounced maximum phase at 75 days from onset. There is also a significant increase of the time spent by each bird in actual song (relative to the rest period) as the peak of the breeding cycle is approached, maxima of T_s, and 'song ratio', occurring at 75 days from commencement.

Turning now to the observed march of singing activity as reflected by the percentage values of the 'song ratio' entered in the last column of Table 1, it is seen that between the sixty-fifth and eighty-fifth days a consistently high level of activity is sustained, the maximum reaching almost 35 per cent at the seventy-fifth day.

It is of further interest to compare the mean values of the 'song ratio' for the whole period of 70 days with that computed from the Cambridge data already mentioned[1]. Table 2 shows clearly that the average song activity found at Sidmouth is about 10 ± 5 per cent greater than the corresponding level of activity for Cambridge.

Table 2. Comparative Song Data for Cambridge and Sidmouth

Locality	Mean song duration (sec.)	Mean rest period (sec.)	Mean song ratio (per cent)
Cambridge (eastern counties)	2·3	15·0	17 ± 4
Sidmouth (south-west England)	2·1	8·2	26 ± 5

Reference to the third column of Table 2 shows that the principal cause of this difference is the shortened rest-period observed at Sidmouth, with an average duration only about one-half of that reported for Cambridge.

These results suggest that significant differences in the level of breeding song activity may well exist between bird populations in different parts of the country, birds native to south-west England, for example, being consistently more energetic songsters than those resident in the eastern counties.

Population Differentiation within Plant Species in Response to Soil Factors

The possible existence of populations within a single species adapted to different soil conditions has long been realized and they have been termed 'edaphic ecotypes'[1]. However, few cases of their occurrence have been described, and very few of these are in relation to soil conditions normally encountered[2], most being in relation to special soil conditions such as in soils of serpentine origin or contaminated by heavy metals[3,4]. This is surprising in view of the fact that a major difference between many closely related species is often that of soil preference.

In an effort to determine if such differentiation occurs within some ecologically wide-ranging species we have used two techniques; first, the effect on growth of contrasting natural soils and, secondly, the analysis of individual factors, which are probably acting in these soils, by a sand-culture technique, thus allowing a more critical approach[5].

The populations so far studied have been: *Festuca ovina* (*a*) from a chalk escarpment at Melcombe Bingham, Dorset, and (*b*) from an acid peat area on the slopes of Pen yr Oleu Wen, Caernarvonshire; *Agrostis tenuis* (*a*) from an acid peat area, slopes of Carnedd Llewelyn, Caernarvonshire, (*b*) from an acid peat area, slopes of Plynlymon, Cards., (*c*) from a moderately base-rich woodland, Ruislip, Middlesex, and (*d*) from a moderately base-rich pasture, Waxham, Norfolk.

When tested in both a Hampshire chalk downland soil and an acid upland peat under greenhouse conditions, yields (dry weight) were as shown in Tables 1 and 2.

These results show conclusively that reaction to the widely contrasting soils is markedly different in the two populations of *Festuca ovina* (soil × population interaction significant at 0·1 per cent level). In contrast to this, however, *Agrostis tenuis* populations show no difference in reaction to the two soils (soil × population interaction not significant).

Some of the populations have also been tested for response to a range of calcium-levels in sand culture.

Table 1. *Festuca ovina* (Total Dry Weight gm.)

Population	Chalk soil	Peat soil	Total
Melcombe	14·58	10·46	25·04
Pen yr Oleu Wen	13·97	15·37	29·34
Total	48·55	25·83	54·38

Sig. diff. at 5 per cent prob., 1·56.

Table 2. *Agrostis tenuis* (Total Dry Weight gm.)

Population	Chalk soil	Peat soil	Total
Carnedd Llewelyn	11·54	19·95	31·49
Plynlymon	11·07	16·13	27·20
Ruislip	11·54	16·23	27·77
Waxham	13·67	22·36	36·03
Total	47·82	74·67	122·49

Sig. diff. at 5 per cent prob., 4·12.

The results are shown graphically in Figs. 1 and 2. There is very good correlation of these results with those of the soil experiment. The calcium-level × population interaction in *F. ovina* is significant at the 5 per cent level and is not significant in *A. tenuis*. It is interesting to note, however, that although *A. tenuis* was not adversely affected by high calcium levels in sand culture, when grown in chalk soil the yield was markedly reduced, symptoms suggesting that an induced iron deficiency was responsible for this.

These experiments, together with preliminary results with further populations of *F. ovina*, clearly indicate the occurrence of edaphic ecotypes within the species *F. ovina*, but no such differentiation in *A. tenuis*.

Similar sand culture work with *Trifolium repens* has yielded evidence of differentiation within this species also. Using populations ranging from chalk downland to base-poor uplands, significant treatment × population interactions in response to both calcium and phosphate have been obtained. By varying the calcium-level of the nutrient solution, it was found that at low calcium (4–8 p.p.m. calcium) upland populations outyielded a chalk downland population, the latter suffering severe calcium deficiency symptoms while the former were quite healthy. At high calcium the chalk downland populations outyielded upland populations. By varying the phosphate level it was found that the chalk and upland popula tions had similar phosphate requirements, and that this was lower than the requirement of a commercia Kent wild white clover.

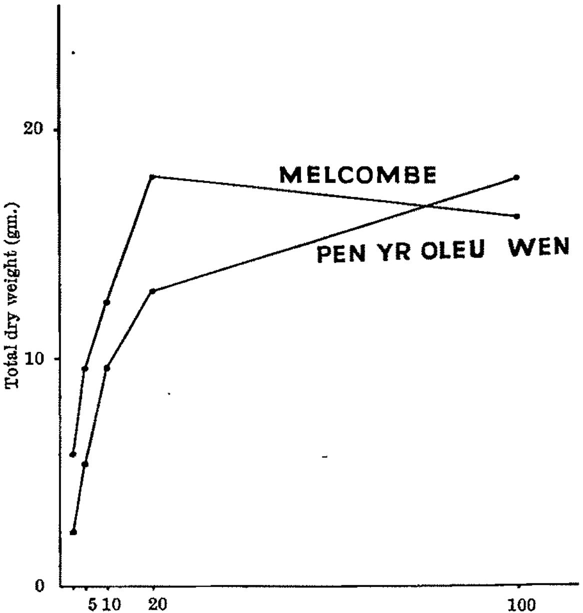

Fig. 1. *Festuca ovina*

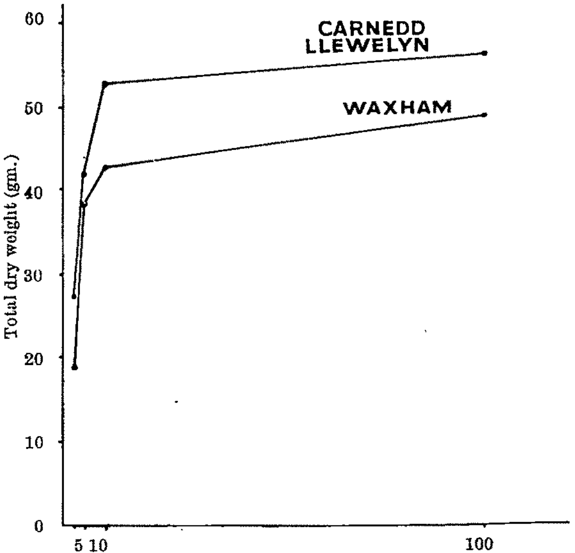

Fig. 2. *Agrostis tenuis*

These results suggest that differentiation in relation to common differences in soil type is more frequen than previously indicated.

This work is part of an investigation supported by a grant from the Agricultural Research Council, to which we are indebted.

Occurrence of Two Characteristic Wealden Ferns in the Jabalpur Series

Plant fossils collected by us during the year 1957–58 from the Upper Gondwanas exposed nea Bansa, South Rewa Gondwana basin, and Sehora Satpura basin, include two well-known Wealden ferns, namely, *Weichselia* Stiehler and *Onychiopsi* Yokoyama. The collection from Bansa includes a few sterile fronds of *Weichselia* sp. (Figs. 1 and 2) The pinnules of these are slightly different from thos of *W. reticulata* in the nature of their reticulat venation. In our specimens the areolæ between th midrib and the margin are more elongate. Both th fertile and sterile fronds of *Onychiopsis* (Figs. 3 and 4 from Bansa resemble rather *O. capsulifera* described by Velenvosky[1]. The specimens of *Onychiopsis* from Sehora are all sterile and resemble rather *O. psilotoides* No *Weichselia* has so far been collected from Sehora

The age of these Upper Gondwana beds exposed near Bansa, Sehora and also at Jabalpur has long been

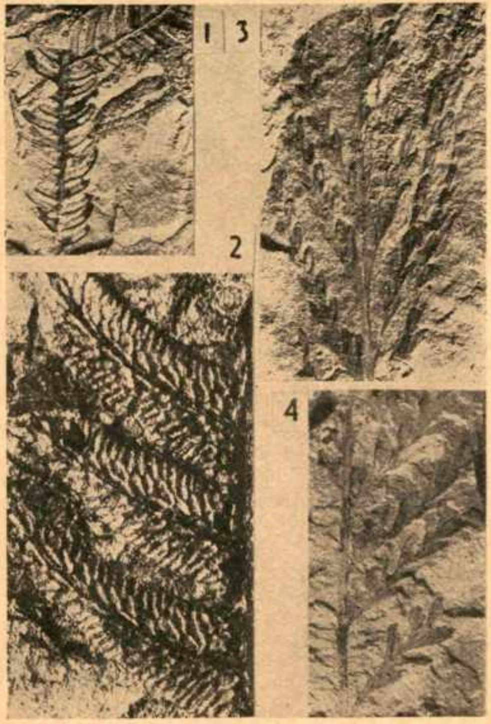

Fig. 1. *Weichselia* sp. (× 1). Fig. 2. Three pinnules of *Weichselia* (× 5). Figs. 3 and 4. *Onychiopsis* sp. (× 1). All the specimens are from Bansa, Madhya Pradesh

in dispute. Three views have been put forward: the first was expressed by Feistmantel[2], who considered them to be Middle Jurassic; the second is by Wadia[3], who regards these beds as Upper Jurassic; and the third is by Matley[4], according to which these are Lower Cretaceous.

On the evidence of the present findings, the age of the Jabalpur series cannot be fixed with absolute certainty. However, considering all the known records of *Weichselia* and *Onychiopsis*, which lie mostly in the Wealden, it is more apt to refer the Jabalpur exposed near Bansa and Sehora to the Lower Cretaceous.

Resistance of *Anopheles aquasalis* Curry to Dieldrin in Trinidad

Work at the Ross Institute with *Anopheles gambiae* revealed that dieldrin resistance is due to an allele of a single gene. When tested with papers impregnated with a mineral oil solution of this insecticide, the heterozygotes for this allele can withstand 0·4 per cent dieldrin for 1 hr. and the homozygotes for this resistant allele can withstand 4·0 per cent dieldrin for 1 hr.

It does not necessarily follow that the same applies to *Anopheles aquasalis* Curry, which is now known to be resistant to dieldrin in Trinidad. However, the same technique was applied using freshly blooded females taken from Shannon dawn traps located in the Barataria area of Trinidad.

On October 10, 1958, using World Health Organization 0·4 per cent dieldrin-impregnated papers, 354 mosquitoes were exposed in 14 World Health Organization kit tubes for 1 hr. and then held 24 hr. At the end of this period there were 339 survivors, which were re-exposed to 0·4 per cent papers for 1 hr. and held for a second 24-hr. period. There were 290 survivors, that is, 81·9 per cent, all of which appeared to be unaffected by the insecticide. 56 mosquitoes in two tubes were used as control, 48 of which survived the same treatment as the test mosquitoes except that the control papers were impregnated only with risella oil.

On October 13, 1958, the test was repeated with World Health Organization 4·0 per cent papers using 377 mosquitoes from the same source. There were 182 survivors, that is, 48·3 per cent. 56 mosquitoes were used as control, of which there were 52 survivors.

It is possible, therefore, from these results that just over 40 per cent of the population tested were homozygous for resistance to dieldrin.

METEOROLOGY

Drift of Toxic Chemicals released from a Low-flying Aircraft

When toxic chemicals, such as herbicides or insecticides, are applied under field conditions, there is a risk that damaging concentrations will occur at distances downwind from the source, and that harm will be done to crops, or to livestock and human beings. Of particular interest is the drift of chemicals released from a low-flying aircraft.

An Auster *J 5G*, a small high-wing monoplane, was fitted with a boom-and-nozzle system which produced a spray with a volume median diameter of approximately 200μ, using dyed Shell 'Diesoline', a liquid for which evaporation is slow at these droplet sizes. The aircraft was flown 10 ft. above the ground in open rolling grassland, and several long runs were made at right angles to the direction of the wind. Relevant meteorological records were kept. Deposits upon the ground were estimated colorimetrically after extraction of the dye from large filter papers, and airborne concentrations, in terms of the amounts passing a vertical area at right angles to the wind, were sampled at a height of 3 ft. by means of cascade impactors[1].

For two such experiments the wind speeds were about 8 ft./sec., and the turbulence factor[2] (F) was -3×10^{-3}. The ground deposits are recorded in Fig. 1, using log–log paper, while Fig. 2 gives comparable results for the airborne concentrations; for ease of presentation the results have been calculated for an emission of 100 c.c. per yard of flight. Despite the scatter of the points, and some shortcomings of technique, particularly in the use of cascade impactors to sample such relatively coarse sprays, reasonably reproducible results were obtained.

The cumulative effect of successive swathes in an area is of interest. With a small aircraft a swathe-width of 15 yd. would be representative of, for

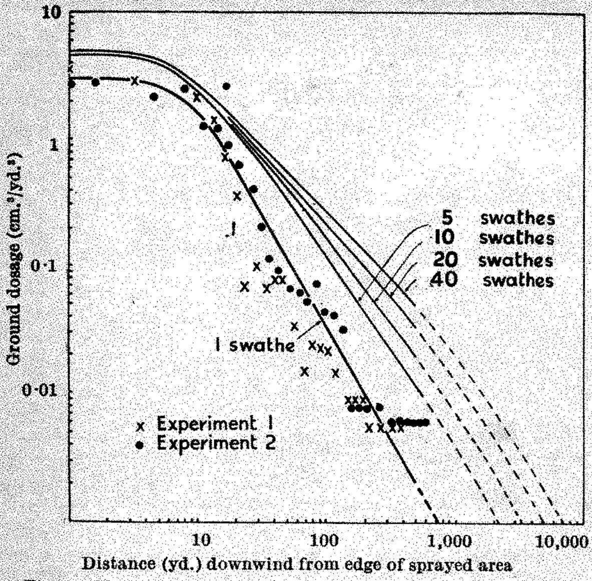

Fig. 1. The variation in ground dosage with distance downwind

example, applications of herbicides in crops, and, using this swathe width and the basic graphs of Figs. 1 and 2, the build-up of dosages has been calculated for various distances downwind from the downwind edge of areas subjected to 5, 10, 20, and 40 successive swathes. An increase in the number of swathes from 1 to 5 increases the ground deposit and the airborne concentration at the downwind edge of the target area by about twice, but a further increase in the number of swathes to 40 results in only a slight further increase. At 100 yd. downwind the swathes are still not additive, the hazard from 40 swathes being only 8–10 times that of one; at 1,000 yd. the hazard from 40 swathes is about 30 times that of one swathe, while it may be inferred that at 10,000 yd. the swathes would be nearly additive, in any event for an involatile liquid.

The results indicate the hazards to be expected for distances of up to a mile or so downwind from a sprayed area. It would be more generally useful to extend the sampling for a few miles downwind, and it is hoped that this will be possible. Variations in droplet size and meteorological conditions are likely to have an effect upon dosage distributions, and their influence is being investigated.

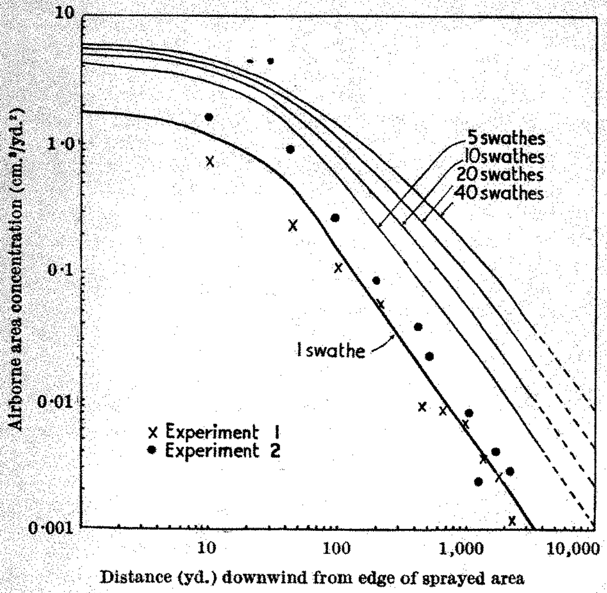

Fig. 2. The variation in airborne concentration with distance downwind

World Variation in Annual Rainfall

The following analysis is based on the figures given by Conrad[1] which cover 358 stations in the belt 60° N.–60° S. The aim of the work was to test the validity of the statement frequently quoted that rainfall variation is much greater in the tropics than in the temperate regions. The broad result of the investigation shows that this is not strictly true.

Conrad has used the mean deviation as the variance factor, v_a, relating this to p, the mean annual precipitation, so that $v_a/p = v_r$. First, the stations were zoned within 20° belts and the differences of the mean of v_r examined.

Table 1. Values of Probability versus Difference of Means of v

	60°–40° N.	40°–20° N.	20°–0° N.	0°–20° S.	20°–40° S.	40°–60° S.
60°–40° N.	—	< 0·001	0·06	< 0·02	< 0·001	>0·2
40°–20° N.	< 0·001	—	< 0·001	>0·2	0·13	0·09
20°–0° N.	0·06	< 0·001	—	0·10	< 0·001	>0·2
0°–20° S.	< 0·02	>0·2	0·10	—	>0·2	0·16
20°–40° S.	< 0·001	0·13	< 0·001	>0·2	—	< 0·02
40°–60° S.	>0·2	0·09	>0·2	0·16	< 0·02	—

Table 1 shows the probability values obtained, and makes clear the fact that there is no significant difference between areas symmetrically placed north and south of the equator. It was therefore permissible to add the respective zones.

Table 2

	Mean of v_r	Variance of v_r	Mean p (mm.)	v_r calculated	n
60°–40° N. and S.	15·5	22·0	799	17·0	125
40°–20°	22·9	110·9	958	16·5	154
20°–0°	19·3	128·8	1,936	15·0	79

From Table 2 it can be shown that the mean of the 40°–20° belt is significantly higher than the other belts, and that 20°–0° is higher than 60°–40°. Conrad has derived an equation connecting v_r and p, and from this v_r was calculated. Columns 1 and 4 in Table 2 stress the fact that it is within the sub-tropics that annual rainfall variation is the greatest.

It was, unfortunately, not possible to test differences of v_r within narrow annual rainfall groups, as the number of stations was too few; but a detailed analysis will soon be made using European and African stations.

J. F. Griffiths

East African Meteorological Department,
Nairobi, Kenya.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, January 12

British Society for the History of Science, Philosophy of Science Group (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. F. Waismann: "Logic and Reality".

University of London (in the Large Chemistry Lecture Theatre, Imperial College of Science and Technology, Imperial Institute Road, London, S.W.7), at 5.30 p.m.—Prof. G. Schwarzenbach (Zürich): "Solution Chemistry of Metal Cations".* (Special University Lecture in Chemistry. Further lecture on January 13.)

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Sir John Hunt, C.B.E., D.S.O.: "Climbing in the Caucasus Mountains of the U.S.S.R.".

Tuesday, January 13

University College (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. H. Kalmus: "Genetical and Cultural Transmission in Animals and Man".*

Institution of British Agricultural Engineers (at 6 Buckingham Gate, London, S.W.1), at 2.15 p.m.—Mr. A. Senkowski: "Ground Adhesion Problems of Wheeled Agricultural Tractors".

Institution of Naval Architects (at the Institute of Marine Engineers, 76 Mark Lane, London, E.C.3), at 5.30 p.m.—Mr. S. J. Jones and Mr. J. K. W. MacVicar: "Development of Air Conditioning in Ships".

Institution of the Rubber Industry, London Section (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. S. E. Bolam: "Compounding Nitrate Rubber for Specific Properties". 7 p.m.—Dr. G. Bielstein: "Some Aspects of High Temperature Vulcanization".

Society of Chemical Industry, Chemical Engineering Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. E. W. Greensmith: "An Organization for Inspection".

Institution of Electrical Engineers, Education Discussion Circle (joint meeting with the London Graduate and Student Section, at Savoy Place, London, W.C.2), at 6.30 p.m.—Discussion on "Education and Training from the Student's Point of View".

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 7 p.m.—Lecture on "Stress Corrosion".

Wednesday, January 14

Society for Applied Bacteriology (in the Barnes Lecture Theatre, Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 10 a.m.—Business Meeting. 10.15 a.m.—Scientific Papers. 2 p.m.—(joint meeting with the Microbiology Group of the Society of Chemical Industry)—Symposium on "Differential Media".

Physical Society, Colour Group (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 3 p.m.—Mr. H. Cole: "The Chemistry of Coloured Glasses"; Dr. R. A. Weale: "Third Thoughts on Cone-Monochromatism".

Institute of Physics, London and Home Counties Branch (in the Lecture Theatre of the Royal Institution, 21 Albemarle Street, London, W.1), at 5.30 p.m.—Sir George Thomson, F.R.S.: "Controlled Thermonuclear Reactions".

Society of Instrument Technology, Data Processing Section (at Manson House, Portland Place, London, W.1), at 6 p.m.—Symposium on "Storage Media".

Thursday, January 15

Physical Society, Low Temperature Group (in the Lecture Theatre of the Royal School of Mines, Prince Consort Road, South Kensington, London, S.W.7), at 4 p.m.—Thirteenth Annual General Meeting.

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. T. P. Hoar: "The Production of Copper and Sulphur by the Electro-decomposition of Cuprous Sulphide"; Dr. E. T. Turkdogan: "Equilibrium Measurements Between Carbon-Saturated Mn-Fe-Si Melts and CaO-Al_2O_3-MnO-SiO_2 Slags".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. B. J. Birch: "Rational Solutions of Equations".

University College, Faculty of Laws (in the Eugenics Theatre, Gower Street, London, W.C.1), at 5 p.m.—Prof. D. Lloyd: "Liability for Radiation Injuries".*

Institution of Electrical Engineers, Utilization Section (in conjunction with the British Nuclear Energy Conference, at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. N. J. Mackay and Mr. E. Hardwick: "Electrical Installation at Calder Hall Nuclear Power Station".

Royal Anthropological Institute (at 21 Bedford Square, London, W.C.1), at 5.30 p.m.—Mr. Trefor M. Owen: "The Bidding and Related Marriage Customs in Nineteenth-Century Wales".

Institution of Mechanical Engineers, Steam Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Boiler Feed Water".

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. G. E. Bessey: "Aerated Concrete".

Institute of Metals (at 17 Belgrave Square, London, W.1), at 6.30 p.m.—Dr. C. E. Birchenall (Princeton University): "The Oxidation of Metals at High Temperatures".

Wool Education Society (at the Royal Institution, Albemarle Street, London, W.1), at 7 p.m.—Mr. A. N. Davidson: "Shrink-Free Wools—a Scientific Achievement".

Chemical Society (in the Large Chemistry Lecture Theatre, Imperial College of Science and Technology, South Kensington, London, S.W.7), at 7.30 p.m.—Prof. J. Baddiley: "Nucleotides and Bacterial Cell Wall Components" (Tilden Lecture).

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Dr. P. E. C. Manson-Bahr: "East African Kala-azar, with special reference to the Pathology, Prophylaxis and Treatment".

Friday, January 16

British Mycological Society (in the Large Physics Theatre, Birkbeck College, Malet Street, London, W.C.1), at 11 a.m.—Symposium on "Some Aspects of Diseases of Vegetables".

Institute of Navigation (at the Royal Geographical Society, 1 Kensington Gore, London, S.W.7), at 5.15 p.m.—Mr. W. J. Charnley: "Blind Landing Problems".

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. J. K. Royle: "Inherent Non-Linear Effects in Hydraulic Control Systems with Inertia Loading"; Dr. D. E. Turnbull: "Response of a Loaded Hydraulic Servomechanism".

Institution of Electrical Engineers, London Graduate and Student Section (at Savoy Place, London, W.C.2), at 6.30 p.m.—Dr. Robert M. Page: "Frontiers of Space Research".

Society of Chemical Industry, Fine Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. E. E. Boake: "Development of Aromatic and Perfumery Chemicals".

Saturday, January 17

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. D. L. Snellgrove: "Buddhist Shrines of Nepal".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer in Electrical Engineering, to teach power and distribution up to Higher National Certificate standard—The Principal, Dudley and Staffordshire Technical College, Dudley (January 15).

Senior Library Assistant (graduate with suitable library experience) in the Science and Social Science Section of the University Library—The Librarian, The University, Birmingham 15 (January 16).

Assistant Experimental Officer (with a degree in science or horticulture) in the Physiology Section—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (January 17).

Experimental Officers, Grade 1 (with a degree or diploma in mechanical, electromechanical or aeronautical engineering fields), at the Weapons Research Establishment, Australian Defence Scientific Service, near Adelaide, South Australia, for duties associated with a group responsible for the design, development and launching of special purpose rocket propelled vehicles—The Senior Representative (A.V.12/6), Department of Supply, Australia House, Strand, London, W.C.2 (January 19).

Senior Lecturer (honours graduate) in Glass Technology at St. Helen's Technical College—The Director of Education, Education Office, St. Helen's, Lancs (January 20).

Assistant Technical Editor (with at least a pass degree in science, technology or arts) in the Ministry of Power, Sheffield, for work on reports and papers concerning safety in mines research—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.266/8A (January 24).

Physicist, Senior Scientific Officer (with a good honours degree in physics, and preferably general physical experience and a knowledge of radiochemical equipment), in the Scientific Branch, L.C.C. County Hall, for research work on properties of materials and in the field of health physics—The Medical Officer of Health (PH/D.1/A), County Hall, London, S.E.1 (January 24).

Lecturer, and an Assistant, Grade B, in the Department of Chemistry—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (January 26).

Soil Analyst (with a degree in chemistry, agricultural chemistry or an equivalent professional qualification from a recognized university or other institution) in the Department of Agriculture, University College of Ghana, to assist in the research programme of the Division of Soil Science—The Assistant Registrar (London), University College of Ghana, 29 Tavistock Square, London, W.C.1 (January 26).

Assistant Lecturer in Applied Mathematics—The Secretary, The University, Belfast (January 30).

Chemical Engineer or Fuel Technologist (with a university degree in science, chemical engineering or fuel technology (with chemistry as a major subject) or equivalent qualifications) in the Coal Research Section, C.S.I.R.O., North Ryde, New South Wales, Australia, to take part in pilot scale investigations on the carbonization of coal in connexion with the Section's research programme into the properties of Australian coals and the improvement of the quality of metallurgical coke made from these coals—Chief Scientific Liaison Officer, Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 480/250 (January 31).

Lecturer in Biochemistry—The Secretary of University Court, The University, Glasgow (January 31).

Lecturer (with a degree in electrical engineering, and preferably experience in one or more of the fields of light current engineering) in Electrical Engineering at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 31).

Lecturer (with an honours degree in civil engineering and preferably research or teaching experience in materials and structures) in **Civil Engineering** at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 31).

Lecturers (2) (preferably, but not necessarily, experience of research work in experimental or theoretical nuclear physics) **in the Department of Physics**—The Registrar, The University, Liverpool (January 31).

Plant Nutrition Officer (with a first-class honours degree in agricultural science or science, or higher academic qualifications, and research experience) at the Western Australian Regional Laboratory, Division of Plant Industry, C.S.I.R.O., Perth, to participate in a programme of pasture investigations in Western Australia—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 135/46 (January 31).

Professor of Inorganic Chemistry—The Registrar, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 32, India (January 31).

Lecturer/Senior Lecturer (with postgraduate experience in veterinary anatomy) **in Veterinary Anatomy** at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 2).

Research Fellow and **Senior Research Fellows** (2) **in the Department of Experimental Pathology**; **Research Fellows** (2) **in the Department of Medical Chemistry**; and a **Fellow, Research Fellow**, and **Senior Research Fellow in the Department of Physiology**, John Curtin School of Medical Research, Australian National University—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1, or the Registrar, Australian National University, Box 4, G.P.O., Canberra, A.C.T. (February 6).

Turner and Newall Research Fellows in Engineering, Inorganic Chemistry, Physics and allied subjects—The Registrar, The University, Manchester 13 (February 14).

Senior Lecturer (suitably qualified and experienced graduate in chemistry or agricultural chemistry) **in the Department of Chemistry and Soil Science**, Imperial College of Tropical Agriculture, Trinidad, West Indies, to teach plant and animal biochemistry to students reading for the B.Sc.(Agric.) degree—The Secretary, Imperial College of Tropical Agriculture, 40 Norfolk Street, London, W.C.2 (February 24).

Assistant Lecturer in Applied Mathematics (Geophysical)—The Secretary, The Queen's University, Belfast (February 25).

Chair of Botany in the University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 28).

Lecturer in Tropical Hygiene—The Dean, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1 (February 28).

Imperial Chemical Industries Research Fellows (2) **in Chemistry, Physics, Physical Chemistry, Biochemistry, Chemotherapy, Pharmacology, Pharmacy, Colloid Science, Metallurgy, Engineering, Geology** or **Agricultural Science**—The Registrar, University of Wales, University Registry, Cathays Park, Cardiff (March 7).

Chair of Mathematical Statistics in the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, March 9).

Lecturers or **Assistant Lecturers** (with experience in at least one of the following fields—generation, transmission and/or distribution of electrical power, measurements, electrical machinery) **in Electrical Engineering**—The Secretary, The Queen's University, Belfast (March 20).

Assistant (preferably graduate in chemistry, biochemistry, or physiology) **in the Department of Pathology**, to help in research in connexion with the investigation of steroids—The Clerk to the Governors, St. Bartholomew's Hospital, London, E.C.1, marking envelope "Research".

Chemist or **Biochemist** (with postgraduate experience and preferably a knowledge of immunochemistry and carbohydrate chemistry), for a wide range of biochemical research concerned with diseases of sheep—The Secretary, Animal Diseases Research Association, Moredun Institute, Gilmerton, Edinburgh 9.

Fellow in the Department of Chemistry, for fundamental research on electron resonance spectroscopy—The Registrar, The University, Birmingham 15.

Laboratory Assistant (preferably with a knowledge of chemistry and experience of handling scientific apparatus), for duties in the Chemistry and Biology Laboratories—The Principal, Coventry Technical College, The Butts, Coventry.

Senior Lecturer (with a wide general knowledge of microbiology and industrial experience, preferably in the food industry) **in Applied Microbiology**—The Secretary/Treasurer, Royal College of Science and Technology, Glasgow, C.1.

SP. 600 SPECTROPHOTOMETER

Visible Advantages

For absorption measurements in the visible region of the spectrum the analyst will find the Unicam SP.600 ideally suited to his purpose. The instrument has a world-wide reputation for accuracy and reliability, and its robust construction and extreme simplicity of operation guarantee long periods of trouble-free service.

The SP.600 is backed by prompt and efficient technical service and, through the series of Unicam Method Sheets, by an advisory service which makes certain that the chemist will obtain full value from this outstanding instrument.

UNICAM
SPECTROPHOTOMETERS

A descriptive leaflet and copies of Method Sheets will gladly be sent on request.

Density-Dependent Factors in Ecology.—Dr. H. G. Andrewartha . . . 200
Preparation and Sectioning of Tissues embedded in 'Araldite' for Electron Microscope Examination.—J. M. Davis . . . 200
A Simple Micro-Stirrer.—R. Morris . . . 201
Salt Excretion in Marine Birds.—Dr. L. Harrison Matthews, F.R.S. . . . 202

PSYCHOLOGY

Colour Vision Phenomenon of a New Class.—Dr. William A. Shurcliff . . . 202

Is this what you need?

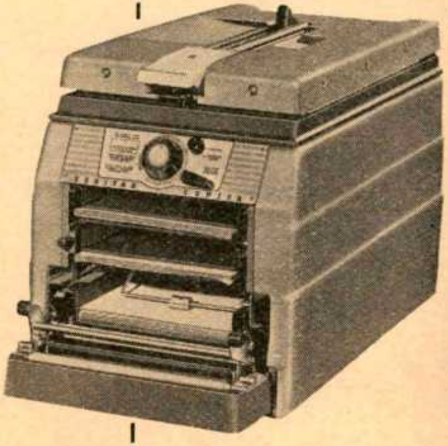
a simple copier

- ★ *that enables everyone to make his or her own copies*
- ★ *that copies everything, including pencilled notes and sketches*
- ★ *that gives you six copies in just over a minute for less than a shilling*
- ★ *that produces* dry *copies, ready for immediate use*
- ★ *that is self-contained*
- ★ *that takes up only a corner of a bench or desk*

The 'Verifax' Copier is used by laboratories and research organisations throughout the country. It is as near perfect for its purpose—*the accurate copying of a wide variety of documents*—as any copier can be.

KODAK *Verifax* COPIER

Copies single documents up to 8½ × 14 inches, and pages from technical journals and books.



Kodak Limited,
Industrial Sales Division,
Kodak House,
Kingsway, London, W.C.2

AUTOMATIC TITRATIONS

ARE easily carried out by the E.I.L. Automatic Titrimeter, Model 24. This instrument is fully automatic, switching itself off on reaching the pre-set end point.

Either the volumetric or the coulometric method may be used, and separate titration units for each type are available. Duplicated connections are provided on the Control unit.

The endpoint setting dial is calibrated in pH and in millivolts, and the equipment can be used for any type of chemical reaction producing a determinate change of e.m.f. The accuracy of titration is 0.05 c.c. in 50 c.c.

AVAILABILITY OF SCIENTIFIC INFORMATION

IN January 1958, important statements regarding scientific publications in the United States, abstracting and the retrieving of scientific information were made to a Sub-Committee of the Congress Committee on Government Operations by such leading scientists as Dr. L. V. Berkner, president of the International Council of Scientific Unions, Dr. W. R. Brode, science adviser to the Secretary of State and president of the American Association for the Advancement of Science, Dr. D. J. Hughes, of the Brookhaven National Laboratory, Dr. H. T. Cox, director of the American Institute of Biologica Sciences, and Dr. Warren Weaver, of the Rockefeller Foundation and the National Science Foundation. Dr. Berkner suggested that absence of knowledge of work done elsewhere was probably the greatest cause of inefficiency in research, but he stressed the value of personal contact between scientists. He went on to recommend that the National Science Foundation should give immediate support to scientific periodicals and specialized publications, to permit and encourage prompt and full-scale publication in English of scientific literature and provide for its abstracting. He also recommended provision for encouraging and financing publication of U.S. Government research papers in recognized scientific periodicals and discouraging unnecessary use of Government research reports. International activities in the publication of scientific symposia and international efforts to improve the publication of abstract periodicals should also be supported, and the translation of scientific papers into English, the unification of translation by different agencies and prompt publication in periodicals regularly acquired by libraries should be subsidized.

With the immediate initiation of substantial and continuing research on subject classification, indexing and procedures for retrieving, designed to provide the scientists of the United States and other Western countries with full access to the scientific literature of the world, Dr. Berkner thought such a programme would repay its cost many-fold. He reiterated his belief that national security is based ultimately on an adequate supply of sound and effective weapons (and men well trained in their tactical use) from a virile industry ; on the recognition and public debate of weaknesses so that they can be corrected ; on a free and unfettered science and technology ; on a free and imaginative industry with full access to all knowledge ; on allies and friends, with whom scientists can deal freely and with a sense of full trust ; and on a society built on the foundations of mutual confidence upon which free enterprise depends. Dr. Berkner, it will be noted, recognizes the need for further sustained research into methods of retrieving information in the widest sense, and in this he was strongly supported by Dr. Hughes, who made this one of his main recommendations.

Dr. Cox, who, like Dr. Hughes, also urged the need to increase the American national effort in fundamental research, suggested it might well be doubled, to a figure of 800 million dollars (including private funds) ; he referred also to the need for investigating new methods for the rapid publication of scientific papers, as well as for the more efficient and cheaper printing of scientific periodicals, but he was concerned as to the danger of excessive centralization and did not view with favour gigantic national centres. In this he was supported by Dr. Weaver, and there was general agreement in these statements that the policy and control of such scientific projects must be in the hands of scientists themselves. Dr. Brode, who stressed particularly the magnitude of the present problem of retrieving information, strongly supported Dr. Berkner's proposal that funds should be available to the National Science Foundation to support studies in this field, but he was hopeful that the President's Advisory Committee on Science might help to solve some of the problems.

Dr. Weaver urged particularly the importance of a careful approach and considered order of priorities, suggesting that the problem would be clarified by the International Conference on Scientific Information which was to meet at Washington in November. We need, he said, to clarify the actual and proper purposes of publication, if only because the recorded word, at best, is a cold substitute for direct communication between scientists, and he stressed the value of removing hindrances to travel. Moreover, it was not simply a matter of communication between scientists themselves, but also of communication between scientists and the public. Dr. Weaver concluded by outlining a programme of public relations with three specific points, which embraced provision through the National Science Foundation of special fellowships for training young men and women in writing, in journalism and in the techniques of mass communication in science so that they could act as a communication link between science and the public ; the provision of funds to assist the American Association for the Advancement of Science to pursue its own plans in this field ; and requiring the major Government agencies concerned with fundamental research to provide intelligible and candid reports of their activities to the public. He reiterated the importance of giving Dr. J. R. Killian, special assistant for science and technology to President Eisenhower, full support, and of using the National Science Foundation and existing agencies to the full. In particular, he thought the Division of Information of the National Science Foundation, with adequate staff and support, would be ideally placed to deal with the information problem.

The Congress Committee was primarily concerned with the availability of information from Federal Departments and Agencies, although, as has been seen, no narrow view was taken of the information problem, and the use of the departmental research report was firmly discouraged by those who gave evidence before the Committee. The scope of the International Conference on Scientific Information at Washington (see p. 147 of this issue) was similar for, although its discussions were nominally concerned with problems of storing and retrieving information, panels examined the literature and reference needs of scientists, the effectiveness of abstracting and indexing services and also of monographs, compendia and specialized centres. Moreover, in his opening address, Sir Lindor Brown was no less searching and forthright than Dr. Weaver in the questions he raised about the purpose of publication, and the need for discipline and critical thought.

Many of the points emphasized before the Congress Committee recurred in the discussions at Washington, notably in those of the panel concerned with the responsibilities of governments, scientific societies, universities and industry for improved information services and research. The panel did not favour the establishment at present of an international scientific information centre, but rather the co-ordination of national services, for example, through national library services. The trend should be for more national centres and more international co-ordination.

The plan, approved on December 7 by President Eisenhower, for improving the availability of scientific and technical information in the United States is entirely in line with the trend of opinion at the Conference and with the views expressed to the Congress Committee last January. It is based on the findings of a report of the President's Science Advisory Committee, of which Dr. J. R. Killian, special assistant to the President for science and technology, is chairman, and Dr. L. V. Berkner is a member. The President's action reinforces the provision of the National Defence Education Act, 1958, which called for the establishment of a Science Information Service in the National Science Foundation to "provide, or arrange for the provision of, indexing, abstracting, translation, and other services leading to a more effective dissemination of scientific information, and undertake programmes to develop new or improved methods, including mechanized systems for making scientific information available". The President has now directed the National Science Foundation to take the lead in co-ordinating scientific information activities within the Federal Government of the United States and has asked all Federal agencies with programmes involving scientific information to co-operate with the National Science Foundation in improving the Government's efforts in this area.

The International Conference alone demonstrated the large extent to which scientific information services present problems common to all nations, even if solutions to particular problems may vary from country to country. This report of the President's Science Advisory Committee is thus of great interest to Britain, and apart from its bearing on the organization of a national library service for science and technology now belatedly under consideration, its clear presentation of the magnitude c the problem and its gravity may well help to convinc those in authority that the projects under consideration in Britain should receive more urgent an generous support than the Advisory Council fo Scientific Policy has yet been able to command The consequences of delay can no longer be ignored and the extent to which responsibility falls on th Government is clearly indicated.

Dr. Killian remarks that there are some 55,00 journals appearing annually, containing abou 1,200,000 articles of significance for some branch o research. In these fields, more than 60,000 different books are published annually, and abou 100,000 research reports remain outside the norma channels of publication and cataloguing. This vas body of scientific information, much of it i languages, such as Russian and Japanese, unknow to most English-speaking scientists, contains th technical data needed by scientists to do their work The rate of increase is indicated by the doublin every twenty years during the past century of th collections of science and technology periodicals i the Library of Congress. These now contain a millio and a half volumes, and about 15,000 are receive annually, with 1,200–1,300 new periodicals appearin each year. By 1979, it is expected that the worl output will reach 100,000 periodicals.

At present a mounting flood of scientific dat threatens to swamp even the most zealous researc investigator; yet our very progress in scienc depends upon the free flow of scientific informatio After reviewing what is already being done in th United States—where the fourteen major scientifi abstracting services are estimated to cover, with thei half-million abstracts, only about 55 per cent of wha is needed for reasonable cover—and stressing a recen trend in the establishment of data centres, th report firmly rejects the proposal to establish single and highly centralized scientific informatio agency, financed wholly or partly by the Federa Government, on the lines of the Soviet All-Unio Institute of Scientific Information.

The President's Committee does not believe tha the needs of the United States, where the researc effort is organized and administered on very differen lines from that of Soviet Russia, would be me effectively in this way. A long-term solution of th problem requires fundamental research into th problem itself and widespread application of mechanical methods and techniques. The Committe considers that the needs of the United States woul be better met by establishing a science informatio service of the co-ordinating type, which woul strengthen and improve the present system b taking full advantage of existing organizations an the special skill of persons with long experience i this field. Such a service, in the best America tradition of private enterprise and Governmen working together voluntarily for the national goo would have two important functions. First, b effective co-ordination of public agencies and privat organizations, it would improve existing facilities and techniques, so as to afford immediate relief to the most urgent short-term problems. Secondly, it would encourage and support the fundamental long-term programme of research and development, with the view of applying modern scientific knowledge to the whole problem, both by the use of mechanical techniques and the discovery of new methods.

Under the first category, the service would assist financially, where necessary, the publication of periodicals and monographs, encouraging also both publishers and scientific societies to experiment with new methods of publication. It would also sponsor and, if needed, support the immediate preparation of world lists of both primary and secondary scientific research publications, classified by subject and indexed, as well as sponsor a list of scientific and technical periodicals and provide a clearing house of information on abstracting and indexing services throughout the whole area of foreign scientific information, expanding the translation of Russian periodicals and initiating additional translation programmes in Japanese and other languages as required.

The service would give special attention to Government scientific reports, expanding the existing system of announcement to include all significant unclassified reports and improving facilities for making copies of these reports available on request. It would also seek to expand and improve throughout the world inter-library exchange agreements, photocopying processes, and other means of bringing to the scientist copies of items unattainable through normal channels. With sufficient funds and support, all this could be attempted at once; but in addition, under the second category, the service would support a continuing programme of research and development through grants and contracts, looking to the widespread application of mechanical techniques to such problems of storage, retrieving, indexing, translating and abstracting.

As already indicated, the Science Advisory Committee does not consider that a new agency is required. The National Science Foundation has specific responsibilities in this field, and a pilot programme has already supplied useful experience and special competence. The Science Information Service could easily be established within the Foundation by extending the Foundation's present programme, and this is the Committee's recommendation and the purpose of the President's action.

It will be apparent from this summary that what is now contemplated in the United States goes far beyond the present activities and responsibilities of the Department of Scientific and Industrial Research in Great Britain. A comparable activity in Britain is that of the Association of Special Libraries and Information Bureaux, which is now turning its attention to the long-term problems of research and development. Further, the Nuffield Foundation has for some time been seeking to foster the examination of new techniques of publication; and Anglo-American co-operation in translating Russian periodicals has already been instituted. The American report demands the considered attention in Britain both of the Advisory Council for Scientific Policy and of the Roberts Committee, which is inquiring into the public library service of the country. Apart from this, it should assist the Parliamentary and Scientific Committee and all who realize the magnitude and seriousness of the whole problem to impress on the Government the need for urgent and adequate action, and for an end to the procrastination and delay that for more than a decade have led to the waste of much scientific effort and man-power.

UNIVERSITY COLLEGE, IBADAN

The Birth of Nigeria's University

By Dr. Kenneth Mellanby. Pp. 263+9 plates. (London: Methuen and Co., Ltd., 1958.) 25*s*. net.

THIS is an autobiographical and personal book. It records the part which Dr. Kenneth Mellanby played for six years as the first principal of University College, Ibadan, Nigeria. When he arrived in 1947 the site was a piece of unsurveyed bush. When he left in 1953 it was a flourishing college presenting candidates for degrees in the University of London and with buildings which many British universities might envy.

Dr. Mellanby writes with sincerity and candour. He makes no secret of the fact that some of his policies were criticized both in Britain and in Nigeria. It is still much too early to judge whether he or his critics were right. Nor does it matter in this book who was right. What matters is the record of what it is like to build a university in tropical Africa, written while it is still fresh in his mind by a man who has built one.

When a university begins as nothing more than two or three square miles of uncleared tropical bush, the first principal (Dr. Mellanby says) must regard himself as expendable. He has no council, no senate, to approve his actions. Every day he has to decide either to do something by unorthodox methods or to run the risk that it will not be done at all. Once the apparatus of academic government is set up, the principal of an African college finds himself to be the point of attachment of three forces which rarely pull in the same direction. London provides money for capital expenditure, coupled with liberal issues of advice which the principal cannot lightly disregard. The local government and Press shower criticism (often only for political reasons) upon the principal; this, too, he cannot lightly disregard. And his own freshly constituted and inexperienced council and senate observe him suspiciously for symptoms of autocracy, and test their untried authority by questioning his policies and slowing down the pace of his pioneering efforts: this force, too, he disregards at his peril.

Dr. Mellanby describes (subjectively of course, because he is still too close to events) what it is like to be acted upon by these three opposing forces. He raises questions which are fundamental to the whole experiment of exporting the English university system to tropical Africa. Chief among these is the question of academic standards: Should academic standards for African universities be from the outset as high as academic standards for the University of London? On one hand many Nigerians would indignantly reject the suggestion that an Ibadan B.A. should be lower in standard than a London B.A.: on the other hand, many Nigerians are impatient that, in a country which needs graduates urgently, so few students graduate from Ibadan and such high standards of entry are demanded. This is one example of the massive unsolved problems which accompany the experiment of exporting the University of London to the African bush. Dr. Mellanby's book is a welcome record of the sincerity and enthusiasm of those who took part in founding Nigeria's university, and the sustained help which the University of London has given to the cause of higher education in the Colonies.

E. ASHBY

FROM CONDUCTORS TO TRANSISTORS

Electric Conduction in Semiconductors and Metals

By Dr. W. Ehrenberg. Pp. x+390. (Oxford: Clarendon Press; London: Oxford University Press, 1958.) 63*s*. net.

THE scope of work on semiconductors has increased in recent years to such an extent that it is no longer practicable for one book to cover the whole field in detail. Dr. Ehrenberg has therefore wisely confined his attention to transport properties, leaving on one side studies of magnetic susceptibilities and surface adsorption (for example), and giving only little space to questions of absorption and emission of infra-red radiation and of X-rays (5 and 3 pages, respectively). If this restriction is granted, it is convenient to treat the subject under the following broad headings.

First, the theoretical basis of band theory and its experimental checks are discussed. This is fundamental for both equilibrium and transport properties. The author spends Chapters 5 and 6 on this topic (65 pages), half the space being devoted to the wave-mechanical problem. He gives a clear introduction which should enable the reader to pass readily to more advanced discussions. This applies in particular to the author's introduction to Bloch's theorem, which he makes plausible in a very simple manner. It also applies to the concept of Brillouin zones, which are introduced by reference to the simple cubic lattice, rather than by more general arguments.

Secondly, an account is given of electron scattering and times of relaxation. Whereas for band theory one could refer the reader to existing standard texts (though, strangely, this is never done in books on semiconductors), this second topic is characteristic of transport phenomena, since it includes the origin of the electrical resistance of materials. The author treats this subject on pp. 55–63 and in Chapters 7 and 8 (a total of 51 pages). A full account of lattice scattering and of the original treatment of ionized impurity scattering is given here, but neutral impurity scattering receives only a brief mention (p. 244).

Thirdly, armed with this theoretical equipment, the author derives more or less formal expressions for the transport coefficients (conductivity, magneto-resistive ratio, Hall and thermo-electric coefficients, etc.), under various conditions of scattering (Chapters 4 and 9, 35 pages). These may then be compared with experiment (Chapter 10, 54 pages). It is good to see that the author has here not restricted himself to germanium and silicon, but has gone on to discuss the older low-mobility semiconductors, on some of which new work is badly needed. On the other hand, results for metals are scarcely discussed, and topics such as the skin effect in metals are also not treated, so that the term 'metals' in the title could be misleading.

The reader should be warned that some of the results in Chapter 4 appear in unfamiliar guise. The reason for this is that the author gives simple but approximate expressions for the Fermi integrals (p. 38):

$$\int_0^\infty \frac{x^n \mathrm{d}x}{1 + \lambda \exp x} \sim \frac{a_n}{\lambda + b_n}$$

where a_n, b_n are numbers, and sometimes uses these in the standard results. The numerical information concerning the a's and b's is new, and, as an error of less than 5 per cent is claimed for $\lambda > 1/6$, it may often be useful.

Fourthly, the author discusses the non-linear properties of semiconductors which have led to their applications as circuit elements, and which are largely responsible for the widespread interest in the whole field. Dr. Ehrenberg has here made a serious effort to give an account of these developments, and has devoted more than a quarter of the book to them (108 pages). He discusses barrier layers and rectification, excess and minority carriers, their life-times, and various types and aspects of transistors. But space considerations clearly did not allow him to discuss the more complicated flow and space charge regimes in transistors.

Because the book is so broadly based, and because the author has read so widely, this is a most useful book which beginners as well as workers in this field will want to possess. The beginner should note that he has not really wasted his time when, after diligent study to p. 33, he reads "The absurd result obtained here indicates therefore a serious misapplication of the model" or when doubt is again thrown (on p. 81) on the preceding work. It might have been simpler if the author had started with what he regards as a satisfactory model (Chapter 5), and if he had introduced those results of Chapters 2–4 which are in fact needed at the appropriate points in the discussion of this model. This would have obviated the two revisions of the model in the first quarter of the book.

Although the preface is dated January 1958, internal evidence suggests that the manuscript itself was completed by 1956. When a subject develops as rapidly as the one here under review, and when the author has evaluated a great deal of recent information, a delay of two years before publication is achieved must be a matter of regret. In spite of this handicap, this book is one of the most balanced and thorough accounts of this field which is at present available.

P. T. LANDSBERG

PROGRESS IN PHYSICS

Reports on Progress in Physics

Vol. 20 (1957). Pp. iv+568. Vol. 21 (1958). Pp. iv+383. Edited by A. C. Stickland. (London: The Physical Society, 1957, 1958.) Each 63*s*. net.

WITH the increasing pace of scientific research, the collection of information regarding recent advances in any specialized branch of investigation is a formidable task and the demand has therefore grown for detailed progress reports and review articles.

The Physical Society, as long ago as 1934, foresaw the need, and the series of annual "Reports on Progress in Physics", which the Society has published almost regularly for the past twenty-odd years, is now a well-established part of our scientific literature and has reached a standard of perfection which many more recent publications are striving to imitate.

Vol. 20 (1957) and Vol. 21 (1958), the two most recent issues in the series, each contain nine independent articles dealing with various aspects of theoretical, experimental and technological physics. The emphasis seems to be, perhaps unavoidably, on theoretical and nuclear physics. The standard of reporting is high and the authors are all experts on, and actively engaged in, the subjects they discuss. The articles vary considerably in length, not always in proportion to the importance of the topic discussed. Vol. 20 contains a long report of 140 pages by R. H. Dalitz on *K*-mesons and hyperons, and Vol. 21 one of the briefest, a 21-page review by D. M. Brink on the theory of collective excitations in nuclei. Every report is accompanied by a very comprehensive list of references.

All research establishments and many research workers are bound to possess their own individual copies of the "Reports". In addition, doubtless many have also purchased separate copies of particular articles, for these are available in paper covers for purchase at appropriate cheap rates. It is therefore not worth while to discuss in detail in this review the contents of the two volumes, but some general comments and reference to one or two articles may be of value. The editors of the "Reports" have in the past impressed on their contributors the necessity to bear in mind the more general reader in addition to the specialist worker, and therefore to preface their articles with an adequate introduction suitable for the non-specialist physicist and to explain fully and simply all terminology and methods used. Not all succeed in doing this, but it is pleasant to report that in the two volumes under review considerable improvement in this respect has been achieved. One or two articles in each volume have an especial appeal for the general reader. In Vol. 20, for example, the review of methods of high-speed photography by J. S. Courtenay-Pratt is both instructive and enjoyable reading, largely because of its numerous illustrations and clear diagrams but also because of the wide application of the new methods in both research and industry. Similarly, in Vol. 21, the report by R. Fatt on the physics of nerve processes, though perhaps not so easy to read, will attract the attention of the physiologist and biologist in addition to the physicist, and the detailed discussion by W. Lochte-Holtgreven on the production and measurement of high temperatures (with an addendum by R. Schall and F. Wecken on high temperatures obtained with chemical reactions), based mainly on the study of thermally excited plasmas with temperatures within the range 10,000–70,000° K., must inevitably have a wide appeal in these days.

Nuclear, atomic and theoretical physics are indeed well represented; but that does not mean that the classical physicist is neglected. For the classical physicist Vol. 20 provides an article by E. R. Dobbs and G. O. Jones on the theory and properties of solid argon, and for the solid-state physicist, "Microwave Properties of Solids" by D. M. S. Bagguley and J. Owen. In Vol. 21, the article entitled "The Specific Heats of Metals at Low Temperatures" by D. H. Parkinson affords a clear and modern treatment of a subject which has been studied extensively since the beginning of the century. During the past decade, moreover, there has been a great deal of activity in the field of low-temperature calorimetry, and most metals now have been examined in reasonable states of purity at temperatures extending into the liquid-helium range. Specific heats, like most thermal properties, are difficult to determine experimentally with precision, and the specific heat of a substance, being a macroscopic quantity, can give only limited information regarding the finer structure of matter. Nevertheless, the general theory of the specific heat of metals which takes into account the contributions of the specific heat from both the crystal lattice and the conduction electrons, and the thermodynamic derivations governing the specific heat of superconductors, are sufficiently straightforward to be within the grasp of honours-degree students of physics. Hence, not only is Dr. Parkinson's report valuable as a stimulant to the research worker to continue investigations in the field of low-temperature calorimetry of metals and in particular in the determination of the shape and position of the Fermi surface, but it is also an important addition to the text-book discussions of specific heats suitable for the advanced or honours course.

In conclusion, it should be mentioned that in addition to its nine reports, Vol. 20 contains a cumulative author index and cumulative subject index to Vols. 16–20 inclusive. S. WEINTROUB

ORGANIC FLUORINE CHEMISTRY

Aliphatic Fluorine Compounds

By A. M. Lovelace, Douglas A. Rausch and William Postelnek. (American Chemical Society Monograph Series, No. 138.) Pp. x+370. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1958.) 100*s.* net.

THE stated purpose of this book is to give complete coverage of all known aliphatic fluorine compounds and to review them comprehensively—a difficult task in this large and rapidly growing field of chemistry. It can be said immediately that this book does not provide the balanced, critical and comprehensive treatise on organic fluorine chemistry that is so badly needed at the present time. The "286 different methods of preparation . . .", "over 60 tables . . .", "physical properties of over 4,500 organic fluorine compounds . . ." summarized in the book are undoubtedly useful; but there is little of the claimed "critical review of the field's systematic progress". The book is a compilation of abstracts of papers and suffers accordingly, summarizing the factual information without propounding the basic reasons underlying the whole field.

The literature is covered thoroughly to 1955, and some 1956 papers are included. The allocation of space among the thirteen chapters (fluorination; alkanes; alkenes and alkynes; alcohols; ethers; ketones, etc.; acids; acyl halides; esters; nitrogen compounds (I); nitrogen compounds (II); organometallics; sulphur compounds) is good and the number of literature references is excellent. The book is well set out and well printed, but in this first edition there are far too many factual, typographical, and proof-reading errors, and clear signs of inadequate checking with the literature; one gets the impression that more use was made of abstracts and a card index system than of the original literature.

Typical errors are as follows: "The bromination of $CF_3CH:CH_2$ at 140° yielded $CF_3CHBrCF_2Br$ and the addition of bromine to $C_3F_7CH:CH_2$ . . . yielded $C_3F_7CHBrCH_2Br$"; ". . . where fluorination of hexafluorobenzene yields $C_6F_6Cl_6$"; "Henne and Zimmer isolated CF_3COOBr and CF_3COOI . . ."; "Roylance, Tatlow and Worthington reacted *o*-dichlorobenzene with CoF_3 and $LiAlH_4$ in ether at 0°"—fortunately they did not, and so live on.

Criticism is always easy, but the presence of numerous errors makes the book difficult to read and often misleading, particularly when errors in physical data occur in the tables. In some places the references are mixed up. One has thus to question continually whether what one has just read is factually correct or not, and how much weight should be given to the evidence. There is no doubt, however, that this could be a most useful compendium, and it is to be hoped that a corrected second edition will soon make its appearance.

R. N. Haszeldine

BRITISH MARINE FISHES

The Observer's Book of Sea Fishes

By A. Laurence Wells. Pp. 160 + 64 plates. (London and New York: Frederick Warne and Co., Ltd., 1958.) 5*s*. net.

This moderately priced little book will enable anglers and others to identify almost all the fishes they are ever likely to meet in British seas, and from that point of view it is a useful addition to a pocket series designed to serve the needs of amateur naturalists and other observers of the things, natural and artificial, among which we live. At the price it may have been impossible to provide an entirely fresh set of pictures, and most of those here were first presented to the public by the same publishers in 1925, in "Fishes of the British Isles" by J. Travis Jenkins. They were not new then, for they were taken from the well-known works of Day (1880–84), Smitt (1892–95) and others. Perhaps it is just as well that a complete set of original illustrations was not attempted, if the unfamiliar (apparently new) coloured pictures on Plates 25 and 36 are fair samples of what might have been. The crude picture of the opah will yet serve for identification, but the misrepresentations of what purport to be corkwing and ballan wrasses will not. The figure labelled corkwing bears but little resemblance to the real thing, while that named ballan wrasse is a travesty of a beautiful fish; it looks as if it might be a copy at second or third hand of the ballan wrasse in Jonathan Couch's four-volume work (1862–65).

The classification and nomenclature are modern but accounts of habits and life-histories are all too often ancient, the author seemingly having derived information too freely and uncritically from Couch (excellent as he was for his day) and other authors of the latter half of last century and the early years of this: he appears to be unfamiliar with much modern work. A few hours in a good library searching through the past thirty or so years of the relatively few scientific English language journals devoted to marine biology and fisheries would have saved him from repeating some hoary legends and would have provided him with much material not yet published in a popular work. Thus, for example, he would have learnt how the angler-fish does use its lure and would not have given what is surely another version of the account by Ælian as quoted by Couch, and he would have been led to modern knowledge of the migrations and breeding of the mackerel. These are but two instances among many which invite criticism.

This book is a lost opportunity, for there is no good modern book, scientific or popular, describing British fishes. There is a very real need for such a book, with authoritative text and new first-class illustrations: the present book provides neither.

D. P. Wilson

MEASUREMENT OF PERSONALITY

Personality and Motivation Structure and Measurement

By Professor Raymond B. Cattell. Pp. xxiv + 948. (London: George G. Harrap and Co., Ltd., 1957.) 55*s*.

In this monumental work, Prof. R. B. Cattell gives a detailed description of the systematic scheme which he has developed for the assessment of personality in terms of the major 'source traits'—those basic personality traits which determine characteristic behaviour and its variations in different individuals.

Three types of data have been utilized: ratings made by associates on forty-two types of behaviour characteristic such as adaptable, cautious, frank, etc.; answers to questionnaires on the same types of behaviour; and scores on a heterogeneous collection of objective tests, including tests of knowledge about interests, predictions of behaviour, perception and recall of related material, projective tests, autonomic reactions and various physiological measures. These data he has submitted to the statistical technique known as 'factorial analysis'; and he terms the factors extracted 'source traits', upon which are based the related types of real-life behaviour and test and questionnaire response. Undoubtedly he has carried out the statistical procedures with enormous care and ingenuity. Some of the factors extracted seem reasonable enough, for example, the motivational tendencies he calls 'ergs', such as 'self-assertion', 'escape', etc. Some of the factors relating to general personal characteristics are also widely recognized, for example, 'cyclothymia versus schizothymia', 'dominance versus submissiveness'; but others are more dubious. However, it is very difficult to accept the existence of some of these 'source traits' as basic personality factors, because of their apparent lack of relationship to the questionnaire and test data from which they are said to be derived. For example, 'premsia', a type of emotional sensitivity which differs from emotional integration, is related to a preference for being a bishop to being a colonel, a lack of physical endurance and a tendency to be brought to tears by discouraging circumstances. Although one can see a possible relationship between some of the personality factors and the associated objective test data, the tests require a much more thorough psychological investigation before their significance to personality can be established.

It is often difficult to follow Prof. Cattell's argument, since it lacks clarity, or to understand how he has used his source data. Though he must be congratulated on presenting a valuable outline approach to these questions, and on the range of data he has amassed; yet far more detailed experimental investigation is necessary before the existence of the 'source traits' and their inter-relationship within the personality is finally acceptable.

Two New Academic Press Journals

Volume 1, Number 1, Spring 1959

EXPERIMENTAL NEUROLOGY

Editor-in-Chief: W. F. WINDLE
National Institutes of Health, Bethesda, Maryland

Associate Editors:

S. L. Clark	L. B. Flexner	H. W. Magoun
E. W. Dempsey	S. S. Kety	R. J. Rossiter

Volume 1, 1959, 6 issues, £5 14s. 6d.

THIS new periodical will publish results of original research by experimental methods; neurophysiology, pharmacology, and chemistry as well as experimental neuroanatomy, embryology, and pathology are the disciplines to be considered. The Editors believe that development and application to the nervous system of the techniques of electron microscopy and of histochemistry will lead to an increasingly large number of reports of an experimental nature.

Manuscripts in the English language and editorial queries may be submitted to the Editorial Office, Room 3D-14, Building 10, Laboratory of Neuroanatomical Sciences, National Institutes of Health, Bethesda, Maryland, U.S.A.

Papers scheduled for publication in the initial issues:

ARTHUR LAVELLE AND FAITH W. LAVELLE, Neuronal Reaction to Injury During Development: Severance of the Facial Nerve Section *in Utero*

LLOYD GUTH and KARL FRANK, Restoration of Diaphragmatic Function Following Vagophrenic Anastomosis in the Rat

C. MURPHY COMBS, Course of Fibers of Brachium Conjunctivum Revealed by Evoked Potential Method

E. J. H. NATHANIEL and C. D. CLEMENTE, Regeneration of Cortical Nerve Fibers and the Fate of Skin and Muscle Grafts Inserted in the Brain

J. M. GIRADO and JAMES B. CAMPBELL, The Innervation of the Urethra of the Female Cat: A Physiological and Pharmacological Study

K. FRANK and J. M. SPRAGUE, Direct Contralateral Inhibition in the Lower Sacral Spinal Cord

Volume 1, Number 1, Spring 1959

DEVELOPMENTAL BIOLOGY

Managing Editor: M. V. EDDS, JR.
Department of Biology, Brown University, Providence, Rhode Island

Editorial Board:

Jean Brachet	Ernst Hadorn	Paul Weiss

Volume 1, 1959, 6 issues, £5

THIS new journal will contain articles bearing on problems of embryonic and post-embryonic development, growth, regeneration, and tissue repair, of both plants and animals. The journal will be international in character, publishing papers in the English, French, or German language.

Papers scheduled for publication in the initial issues:

JEAN BRACHET and M. DELANGE-CORNIL, Recherches sur le Rôle des Groupes Sulfhydriles dans la Morphogénèse

A. MOSCONA, Squamous Metaplasia and Keratinization of Chorionic Epithelium of the Chick Embryo in Egg and in Culture

YASUA HOTTA, SZOZO OSAWA, and TOMOHIKO SAKAKI, Ribonucleic Acid and Differentiation of the Gametophyte of a Polypodiaceae-Fern

ROLF LOOSLI, Vergleich von Entwicklungspotenzen in Normalen, Transplantierten, und Mutierten Halteren-Imaginalscheiben von *Drosophila Melanogaster*

A GEOMETRICAL APPROACH TO THE STRUCTURE OF LIQUIDS*

By Prof. J. D. BERNAL, F.R.S.

MOST of the vast literature on the liquid state is based on attempted explanations of experimental observations of the thermal, mechanical, and other properties of actual liquids. Compared with the progress of the molecular theories of gases and the lattice theory of crystalline solids, there has been little success in accounting for the phenomena of the liquid state in terms of the position and the known laws of the interaction of their constituent molecules. This is evidently because of the extreme difficulty of arriving at a model of the structure of a liquid which corresponds to the arrangements of its molecules and which at the same time is susceptible to mathematical computation. Most recent theories[1] are frankly attempts to adapt the known structures of gaseous and crystalline matter to the intermediate state of the liquid. They are consequently physically very implausible, whether they are the kinetic multiple molecular contact theories of Kirkwood[2], Born and Green[3], the cell theories of Lennard-Jones and Devonshire[4], the hole theories of Frenkel[1], Eyring[5] and Furth[6], or the cybotactic hypothesis of Stewart[7]. The last three indeed assume that a large part of a liquid consists of crystalline material, which is in contradiction to the essential negative property of liquids—their lack of long-range order.

Meanwhile, evidence on the actual molecular structure of liquids has been accumulating, starting with the classical work of Prins[8] and Stewart[7] based on X-ray, and now on neutron, diffraction of liquids[9], which shows them to possess only a short-range order, practically limited to molecules in the first and second spheres around a given molecule. Very little use has been made of this evidence in constructing theories of the liquid state, essentially because of its complexity—of a kind unfamiliar to theoretical physicists or chemists.

It has occurred to me recently that, in view of this and a renewed interest in the properties of liquids, it might be worth while to take up the sketch of a theory I first put forward twenty years ago[10], and to see whether it is capable of leading to a physically acceptable theory of liquids. I cannot yet claim that it is at the same time adapted to mathematical treatment, but I have hopes that at least it can be adapted to computing machines in the way that has already been used by Alder and Wainwright[11] for kinetic studies of gases.

The essential feature of this theory is that it treats liquids as *homogeneous*, *coherent* and *essentially irregular* assemblages of molecules containing no crystalline regions or holes large enough to admit another molecule. In most of what follows I shall be dealing with ideally simple liquids such as those of the rare gases (except helium), but the arguments used can apply with minor modifications to all liquids. What characterizes any particular liquid arrangement is its radial distribution function $g(r)$ which expresses the probability of finding a molecule at a distance r from any other. The determination of the distribution function from diffraction data is subject to error in detail, but its main features are beyond doubt. All show a strong peak indicating 8–12 neighbours at a distance r_0, very little different from the closest approach in the corresponding crystalline solid. The interpretation of the structures corresponding to any radial distribution function is an exercise of an almost unknown subject, 'statistical geometry', which I recommend to mathematicians. There must be theorems limiting the possible forms of distribution functions of any array of points whatever. For example, in a dense irregular assembly, each point is linked in general by fourteen vectors to its neighbours, while only six are needed to fix its position precisely, each vector being counted twice. It would be most desirable to find the true minimum number of parameters or parametral functions defining the statistical structure of any homogeneous irregular assemblage in the way that the lattice vectors define a regular one. I suggested—but could not prove in my original paper—that three parameters suffice to determine the whole of a distribution function : N_1 the number of neighbours, r_1 the mean distance, and λ_1 the variance of r between the neighbours. Whether this be so or not geometrically, it is evident that physically most of the properties must be determined by the arrangement of neighbouring molecules, on account of the rapid fall-off of attractive intermolecular potentials as $1/r^6$ for apolar molecules.

What I am attempting to do now is to examine more closely the neighbour relations in irregular assemblies of molecules. In any definite assembly of points whatever, the neighbours of any one point can be precisely indicated. If planes are drawn bisecting the distances between each point and any other, then we can call those points corresponding to the sides of the smallest convex polyhedron surrounding the point the *geometrical neighbours* of the point[17]. There seem to be, in irregular as in regular arrangements, some fourteen of these, and in any approximately dense assembly of molecules, they will lie between r_0 and $\sqrt{2}r_0$, where r_0 is the distance of closest approach. In the ball-and-spoke model (see below), this number was found to be 13·6 and in the 'Plasticene' model 13·3.

Many of the properties of liquids can be most readily appreciated in terms of the packing of irregular polyhedra—as in a foam (Fig. 1). For example, the total volume V of a liquid of n molecules is Σv_q, where v_q is the volume of the q^{th} molecular polyhedron. To obtain an expression for v_q, or rather for $\bar{v}$, the mean polyhedron volume, in terms of molecular dimensions and arrangement, it is not convenient to use the number of geometrical neighbours, which is insensitive to these factors. It is easier to use the number N of *physical neighbours* which can be defined, arbitrarily, as those of the geometrical neighbours which lie at distances between r_0 and 5/4 r_0 (for beyond the latter distance the Van der Waals attraction falls to less than a quarter of its maximum value). The mean volume can then be expressed as $r_0^3 \mathrm{f}(N)$, where $\mathrm{f}(N)$ is a function not yet

---

The equivalences of N with reduced temperature T^* are derived from de Boer's results (ref. 20).

The irregularity of the neighbourhood polyhedra is the essential condition for liquid as against crystalline structures. It can be seen to underly their thermal and mechanical properties. It implies first of all the absence of long-range order and of symmetry other than statistical. The conditions that a set of quasi-equal irregular polyhedra must satisfy to fill space completely must be stringent, but I have not been able to define them mathematically. Instead I have tried to approach them by physical and mathematical model-building in a somewhat different way from that employed by Morell and Hildebrand[12]. In the first place, I have constructed models of balls and spokes as irregular as possible using spokes of lengths from 2·75 to 4·0 in. in the proportions roughly the same as observed in liquid distribution functions (Fig. 2). From such models it is possible to draw conclusions on volume and energy of the corresponding arrangements of actual molecules. I have also built models from which the human element is eliminated so far as possible by 'Monte Carlo' constructions. The first of these which I attempted ten years ago was purely mathematical. I operated on a pseudo-lattice with a possible cell content of 100 unit spheres in close-packing. Into this I inserted such spheres in random positions, rejecting all those that would foul earlier positions. After inserting less than fifty spheres there was no room for another. Hence the volume per molecule was more than twice that in close-packed arrangement. This led me to abandon the effort, for it was clear that this random-packed assembly could not be the model of a liquid of volume only 10 per cent more than close packed. I see now it was the model for a liquid approaching its limit of coherence at, or above, the critical point.

The second 'Monte Carlo' approach I have tried with physical models is analogous to the formation of irregular close-packed liquids by compression from a gas. A set of points is chosen at random in the large cell of a two- or three-dimensional lattice (Figs. 3 and 4). If these are thought of as being rigid spheres of unit radius, the compression of such a cell is exactly equivalent to expanding a sphere surrounding each point. No new points are added. Starting with the nearest pair, the points are moved apart by small successive stages so that at each stage no two points are nearer than a pre-specified distance. There is a limit to the process, however. At a length corresponding to about 0·9 of the close-packed distance in two dimensions and 0·95 in three dimensions, no further movement is possible without introducing long-range order. In other words, at densities beyond a certain limit, only crystalline arrangements of incompressible spheres are possible. Two-dimensional

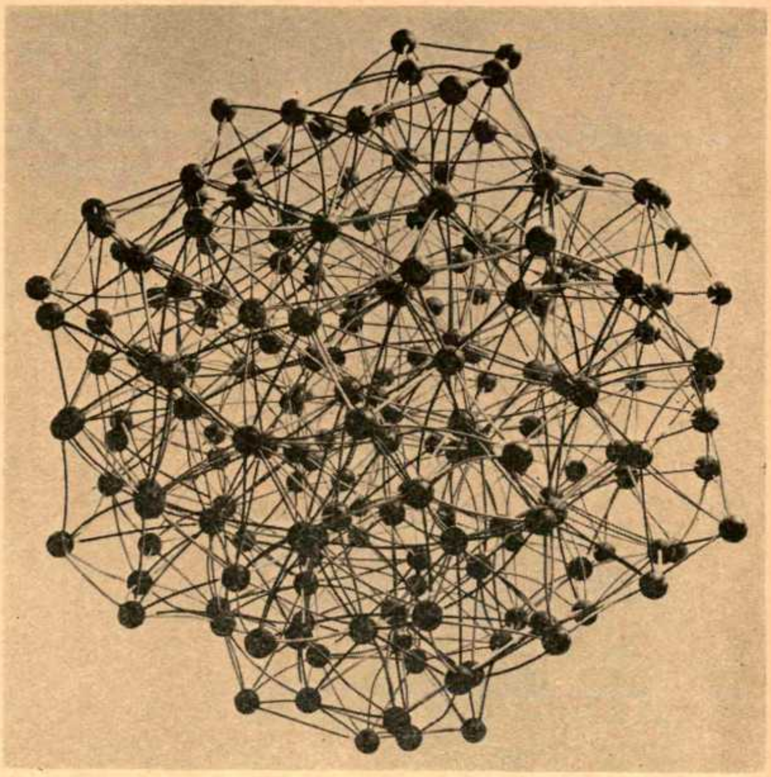

Fig. 2. Photograph of ball-and-spoke model of irregular structure. Spokes of different length are distinguished by colours

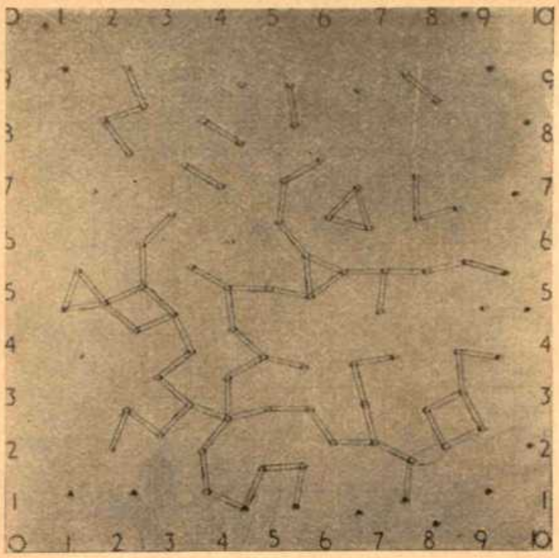

Fig. 3. Two-dimensional random/crystal model at intermediate stage. No two points are at a distance smaller than the 8-cm. long links joining most of the points

aggregates crystallize more easily than do three-dimensional aggregates. This is a point of the greatest importance, because the possibility of irregular co-ordinations are multiplied in three dimensions. The whole process of compressions can be carried out by rules adapted to the iterative action of an electronic computer; but this has yet to be done, and it may turn out to be blocked by the occurrence of impossible moves or 'moving corner' ambiguities. However, enough has been done to bring out clearly that indefinite irregular assemblies can be constructed having about the same volume, internal energy and distribution function, as tested by the Lipson diffractometer, as simple liquids. The possibility of forming such statically stable, dense irregular molecular aggregates in three dimensions follows indeed from the great variety of polyhedra of 10–14 sides that can be escribed about the same sphere. Such arrangements, though they must have slightly greater energy than the corresponding regular assembly, are so much more numerous as to provide for greater entropy.

I have also attempted to describe the irregular character of such distributions both mathematically and by models. I am reasonably sure that the enumeration of topologically distinct convex polyhedra having in general three edges meeting at a point must have been carried out by some mathematicians, though I cannot trace it. The subject appears not to be of interest to modern mathematicians, and I have found little on it later than Cayley[13] and Kirkman[14], who were only interested in symmetrical solutions, except in the very valuable studies of Toth[15]. The derivation of the irregular polyhedra is straightforward but tedious. There are certainly 46 distinct polyhedra with up to 12 faces composed of polygons of 4, 5 and 6 edges (Fig. 5). There are probably, though I have not exhausted the list, some 150 of up to 14 faces. To work out the angles and closest approach of spheres to all these would be a formidable task. Before attempting it I thought it would be well to discover which of them were likely to occur in nearly close-packed assemblies of spheres. For this I used a rough empirical method adapted from that developed by the botanist Marvin[16] to determine the shapes of cells in plants. Balls of 'Plasticene' rolled in chalk were packed together irregularly and pressed into one solid lump. The resulting polyhedra (Fig. 6) were analysed for arrangement of their polygon faces, with the results shown in Table 2. Two results are noticeable: first, the wide variety of polyhedra—the 65 studied showed 32 different combinations of polygonal faces and only two were found with the same permutations of these faces; secondly, the absolute predominance of pentagonal faces. In all but six cases, no polygon appeared more often than a pentagon. These observations, taken together, are the key to the geometrical nature of irregular aggregates of equal spheres and also, in my view, of the molecular arrangements in liquids. Regular three-dimensional arrangements have symmetries limited to multiplicities of 2, 3, 4 and 6. Pentagonal arrangements can only occur in very complex structures such as some of the alloy structures classified by Frank[17].

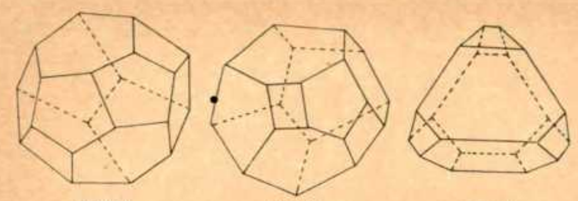
Table 2. NUMBER OF EACH POLYGON COMBINATION TYPE ARRANGED IN THE ORDER OF THE NUMBER OF PENTAGONAL FACES

Number of pentagonal faces :									
12	10	9	8	7	6	5	4	3	1
0 12 0 (2) 0 12 2	1 10 2 (4) 1 10 4 (2)	1 0 9 3 2 9 5 1	2 8 1 (2) 2 8 2 (3) 2 8 3 (3) 2 8 4 (4) 2 8 6	3 7 2 1 (3) 3 7 3 1	3 6 2 3 6 3 (5) 3 6 4 (5) 3 6 5 (3) 3 6 6 (5) 4 6 4 2	1 2 5 3 4 5 3 1 4 5 4 1 (2)	1 3 4 3 1 1 3 4 4 1 (2) 1 3 4 5 1 (3) 1 3 4 6 1 4 4 2 4 4 4 4 4 5 4 4 6	5 3 3 1	1 4 1 5
3	6	2	13	4	20	4	11	1	1

Total number of polyhedra, 65. Number of polyhedron categories, 32

Explanation: The numbers for each polyhedron are put in the order of the polygonal faces. For example, 1 3 4 5 1 stands for a polyhedron with 1 triangular, 3 quadrangular, 4 pentagonal, 5 hexagonal, 1 hepagonal face. The last row gives the number in each category.



282(2) 363(1) 525(m)

Fig. 5. Three typical polyhedra with twelve faces

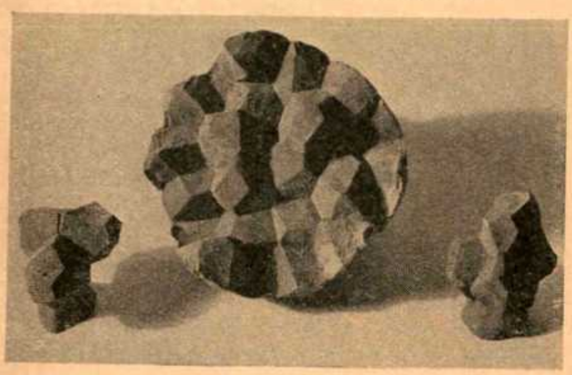


Fig. 6. 'Plasticene' hemisphere showing polyhedra

My central geometrical thesis is that *irregular dense packing and pentagonal arrangements are necessarily connected*. Though I have no proof of this theorem for lack of an adequate statistical geometry, I think it is related to two simple geometrical facts: first, that twelve spheres touching an equal sphere are most regularly distributed in a way in which one just fails to touch five others in its shell—it has a surface co-ordination of 5, to follow Frank's terminology. This results in a pentagonal icosahedron, a shape which cannot be used to fill space. Secondly, in those forms which can fill space, the twelve co-ordinations corresponding to hexagonal or cubic close packing, each sphere is in actual contact with only four others in its shell, a very stable but improbable arrangement. This is on the basis of a rough examination of the number of possible arrangements of 10–15 circles on the surface of a sphere. This may be susceptible to exact statistical treatment, or could be adequately worked out on a computer.

The irregular dense arrangement occupies a volume per sphere of some 10 per cent more than close packing. This is the figure first found by Osborne Reynolds[18] in his studies of the dilatancy of close-packed sand.

I have always found it impossible to construct irregular arrangements of any intermediate density. I believe this is a necessary consequence of the irregularity, and that there is *an absolute impossibility of forming a homogeneous assembly of points of volume intermediate between those of long-range order and closest packed disorder*. Regular and irregular close packing are evidently arrangements of quite different local co-ordination, and a transition between them is necessarily as abrupt as that between two regular phases of different structure such as occurs in the α-(body-centred) and γ-(face-centred) phases of iron.

Translated into physical terms, this geometrical difference expresses the absolute discontinuity between the liquid and the crystalline phases and accordingly the need for a first-order transformation between them. This is in accord with Simon's general findings[19] that the melting entropy of solids increases indefinitely with the temperature, showing therefore no tendency towards a critical point. The fact that the polyhedra of irregular and regular packing differ only slightly in volume for the same values of N would seem to justify, at least as a working hypothesis, the idea that a liquid structure near the melting point is only an irregular but absolutely distinct variant of a crystalline one. In this irregular structure, molecules are vibrating about positions of equilibrium for times so long compared to their period of vibration that for all thermal properties the time variations of molecular positions—so important for all transfer phenomena—can be neglected in the first instance. The lower specific heat of simple liquids compared with the corresponding solid at the same pressure is accounted for by the irregular and wider shape of the equilibrium minima: at constant volume there is little difference between the specific heats of solids and liquids. On this basis, finding the equilibrium structure of a liquid is the same as finding that of a crystal. For liquids having molecules with attraction rapidly diminishing with distance—such as rare gases and organic liquids, but not for liquid metals or water—the solution equates minimum energy with minimum volume. If the internal energy U varies as $1/r^6$, it must vary as $1/v^2$, as Van der Waals had intuitively supposed. The types of irregular arrangement arrived at by all the methods described above, except that leading to maximum coherent volume, are of minimum volume and should be near to true models for a liquid near the melting point. Indeed, by using a potential function of the form $U = \frac{A}{r^{12}} - \frac{B}{r^6}$ they are found to give the right orders of magnitude for the heat of fusion.

The chief advantage that a theory based on the intrinsic irregularity of liquid structures has over most cell or hole theories is that it gives a natural qualitative explanation for the high entropies of liquids compared with solids which these theories have failed to do, as de Boer[20] has pointed out. Unfortunately, it is not yet possible to put this on a quantitative basis. The fundamental difficulty is to know what to count as a configuration in order to build a partition function. It is evident that in an irregular structure there is a wide variation in the potential energy associated with each molecule. The extent of this variation, drawn from the first model structure and from the 'Plasticene' polyhedra, is shown in the histograms (Fig. 7).

It may be possible to make use of these differences to build a partition function somewhat on the lines advocated by Kikuchi[21] for another liquid model; but even without this, we can make a qualitative picture of the energy states in a liquid as a function of temperature. In the first place, from near the melting point downwards through the range of supercooling, the approximate close-packed disorder is maintained, for it cannot change without crystallization, which, for the reasons already given, is always a discontinuous phenomenon. However, at all temperatures the thermal state of a liquid is fundamentally different from that of a solid, for the rise in temperature leads not only to higher vibrational levels, as it does in a solid, but also to changes in the equilibrium configuration, increased disorder, and, at constant pressure, also to greater volume, lower co-ordination numbers and consequently lower mean-lattice energy. A liquid, over this range of temperature, corresponds more to a series of polymorphic phases with heats of transformation between them

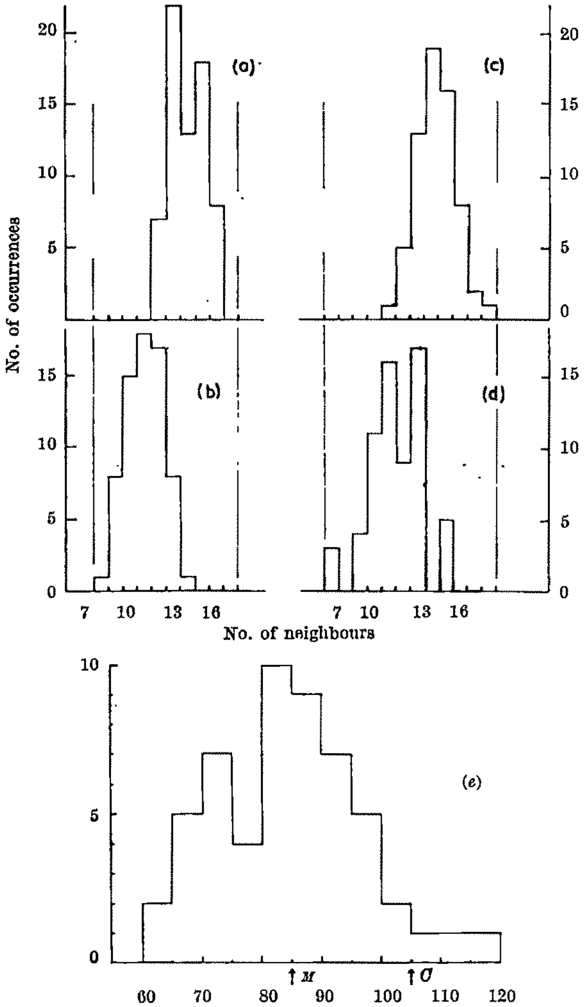

Fig. 7. Histograms of (*a*) geometrical and (*b*) physical neighbours derived from 'Plasticene' polyhedra; (*c*) and (*d*) derived from the wire model. (*e*) Distribution of energy between balls in wire model in arbitrary units. *C*, energy of corresponding crystal; *M*, mean energy of liquid

than to a single phase, as explained in my original paper[10]. Instead of heats of transformation, the process is smeared out to give an accelerated rise in the specific heat at constant pressure which I called the 'configurational specific heat'.

This has been recently studied in detail by Jones and Walker[22] for liquid argon. Their observations of the specific heat seem to me of fundamental, but hitherto unrecognized, importance. They find that, well above the critical pressure, the specific heat at constant pressure, starting at 10·8 cal./mol./deg. C., increases rapidly with temperature to values of nearly 50, reaches a sharp maximum and then falls to the normal value 3 for a gas. This is the condition for a higher-order transition (λ-point) between the liquid and the gaseous state. The line of transition in the pressure-temperature diagram continues that of the boiling-point line indefinitely beyond the critical point. I would suggest calling this line the *hyper-critical line*. Its existence shows that liquid and gas do not form, as previously thought, a single 'fluid' phase. They are distinct states of matter, though one may pass into the other without visible discontinuity. (The discontinuity is, however, 'audible', as shown by heavy absorption of sound in this region and is also shown by a minimum in the velocity of sound and in the viscosity.) This is probably a very general phenomenon applying not only to all liquids and gases but also to all critical mixtures above their critical points.

It finds a ready explanation along the lines of the theory I have just been putting forward. In this picture, a liquid will continue to expand with temperature until it is slightly more than three times its original close-packed volume. The *physical* co-ordination number falls to between 4 and 3, which is the limit for 'coherent' structure—one in which the molecules are linked together without a break throughout the whole volume (Table 1 and Fig. 8). Above the hyper-critical temperature it becomes 'incoherent', consisting of associated groups of molecules in free space. As this temperature is approached, therefore, at constant pressures at or above the critical pressure, more and more co-ordination links are broken, leading to a rise in specific heat. This falls again beyond the hyper-critical point as fewer and fewer links remain to be broken. Just below and above this temperature, the number of intermolecular links undergoes no abrupt change; hence there is no heat of transformation, but continuous regions become discontinuous and vice versa. This is analogous on a micro-scale to the sharp transition between oil-in-water and water-in-oil emulsions. At temperatures and pressures approaching the critical point, the coherent–incoherent structures become also inhomogeneous with macroscopic cavities and drops leading to the critical opalescence, the study of which has been recently taken up again by Debye[23].

The fundamental structural characteristic of liquids—the irregular arrangement of their molecules—can be seen also to be the basis of their characteristic physical property—their fluidity. In a way impossible for a crystalline solid, the neighbourhood relations of molecules in a liquid are necessarily in continual flux. This is easiest to understand by considering the relationships of the polyhedra which define the closest interacting neighbours. The elementary process by which a molecule loses a neighbour is represented by the closing in of the face common to both; how it gains another is by the opening up of a new, in general, triangular face (Fig. 9).

Such processes must occur constantly by thermal motion on account of the sustained inequality of energies between molecules. By repetition they give rise to self-diffusion and show themselves on the macroscopic scale in fluidity. In this view, the *fluidity of a liquid is a consequence of its molecular*

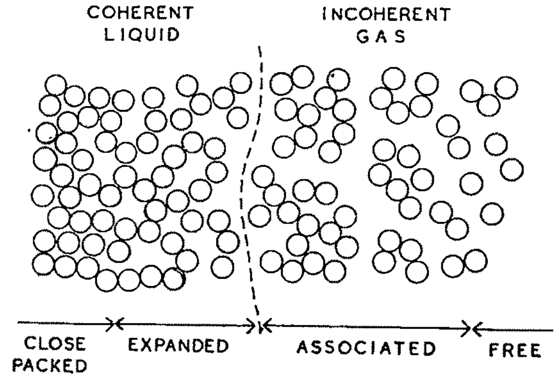

Fig. 8. Diagram of transition of molecular arrangements passing from close-packed liquid to gas through the hyper-critical line

irregularity and not vice versa. The construction of a theory of viscosity based on such a mechanism would be formally almost identical with that of Eyring[5], based on the hole theory and the analogy to rates of chemical reaction. Another consequence of the intrinsic irregularity of liquid structures is their powers of accommodating molecules of different sizes, and consequently accounting for the solvent powers of liquids and their mutual miscibility.

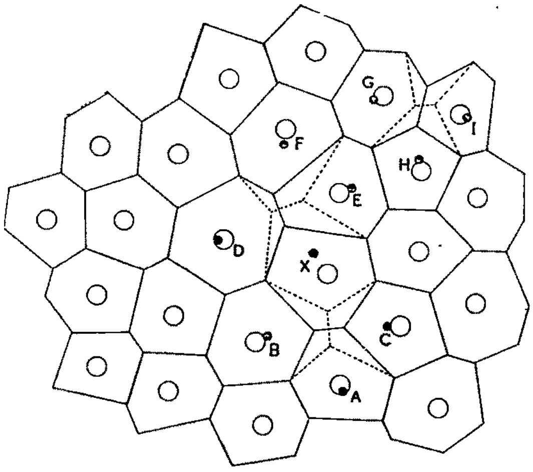
This picture of the liquid state, based on the properties of the simplest spherical molecules such as those of the rare gases, is readily extended to other types of liquid. It can take into account the effects of shape, as in most organic liquids (for example, it would explain the quasi-crystallinity of two-dimensionally packed long-chain hydrocarbon molecules); the presence of hydrogen bonds, as in water, alcohols and acids, leading to the formation of non-equilibrium liquids or glasses; the presence of oppositely charged ions, simple or complex, as in fused salts where low co-ordination[24] also leads to glasses; and that of free electrons, as in metallic liquids where, as I have already proposed[25], the metal ions occupy a smaller part of the volume, leading to greater fluidity and smaller change of volume on melting.

This theory, or rather sketch of a theory, of liquids is put forward not because it accounts better for their properties than the numerous formal mathematical theories that have been in use in the past twenty years. The success of many of these, often radically different from each other, only goes to show how insensitive to theory are such expressions as the equation of state or the laws of viscosity. I am putting it forward rather because, as a crystallographer, I find it more satisfactory to try to build theories of liquids on the basis of a model of an instantaneous molecular structure that is at least plausible. I feel that we now have ample evidence that the essential nature of the liquid state is the existence of statistical molecular configurations with varieties of co-ordination patterns geometrically necessarily different in kind from any that can occur in a regular solid. Any theories that do not take this into account—and few have hitherto—are likely to lead to predictions which are the wider from the facts the more the properties concerned, such as vapour pressure or critical constants, depend directly on the molecular arrangements.

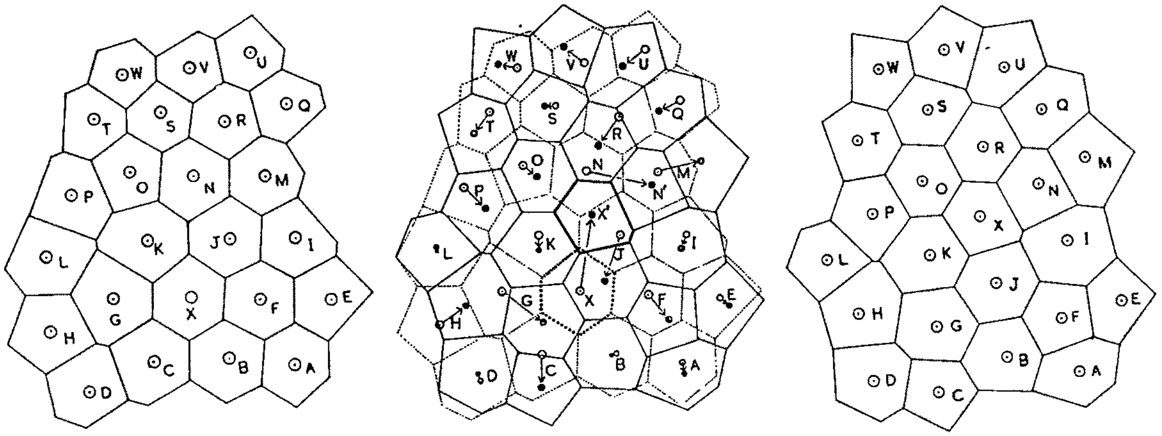
What I have done, and I hope even more the programme of research that should follow it, should show that an approach to a theory of liquids based on irregularity is not so formidable mathematically as to discourage quantitative studies. If this should prove to be the case, it seems probable that the new theory should not only explain known facts but also point the way to unsuspected new phenomena.

Note added in proof: Prof. F. C. Frank has directed my attention to the important papers by C. S. Smith[26] and L. J. Meijering[27] on the shapes of crystals in a polycrystalline solid. The former, by experiment, finds the average number of geometrical neighbours to be 12·48; the latter calculates, by an elegant method, that for a completely random distribution of nuclei it should be $48/35\pi^2 + 2 = 15{\cdot}54$. This is clearly greater than the numbers observed and would seem to indicate that the distribution of nuclei is not random. This, however, does not affect the argument above, for the *average* number of edges on the faces of such polyhedra only varies from 5 to $5\frac{1}{4}$ when the number of faces changes from 12 to 16. An alternative version of the general thesis of the paper could be put in the following form:

"In the most probable arrangements of densely packed spheres the *mode* of the surface co-ordination will be the same as the *mean*, or nearly 5. As this



(a)



(b)

Fig. 9. Diagram to illustrate molecular movements in liquids through neighbour exchange: (a) illustrating individual moves; (b) illustrating the extent to which one molecule can be displaced after five moves. (The two-dimensional representation greatly exaggerates the distortion required for a single move)

is incompatible with long-range order, the corresponding arrangement of molecules must be a fluid."

INTERNATIONAL CONFERENCE ON SCIENTIFIC INFORMATION

THE National Academy of Sciences–National Research Council in Washington was co-sponsor with the U.S.A. National Science Foundation and the American Documentation Institute in arranging an International Conference on Scientific Information during November 16–21 in the Mayflower Hotel, Washington. The Conference opened with an address from Sir Lindor Brown, biological secretary of the Royal Society, and this was followed by a series of sessions, each of three hours, devoted to a section of the Conference subjects. The purpose of the Conference was to bring together scientists and information specialists for discussions of current research and problems concerning primarily the storage and retrieval of information. This is a narrow scope compared with the Royal Society Conference on Scientific Information Services held in 1948. Nevertheless, preprints of seventy-five papers occupying 1,420 pages were circulated to all participants some weeks before the Conference. These participants numbered about one thousand, and for the purpose of facilitating discussion the authors and members of seven discussion panels, each of 9–13 persons appointed well in advance of the meeting, were grouped in a forward section of the Conference hall and permitted to comment throughout the meeting. The remainder of the participants were silent observers during the sessions, but there was ample opportunity for discussion outside the Conference hall and in the neighbouring hall, which housed an exhibition of modern storage and retrieval systems devised by commercial organizations. A small historical exhibit illustrating the Royal Society's long and continuing interest in scientific information services was also on view. Arrangements were made for organized visits to institutions in Washington concerned with the retrieval of information. These included the Library of Congress, the U.S. Patent Office, the National Bureau of Standards Data Processing Systems Division, National Library of Medicine, the Department of Agriculture Library and the Institute of Languages and Linguistics of Georgetown University, where a machine translation of Russian texts in organic chemistry using an I.B.M. 704 computer was demonstrated.

Sir Lindor Brown in the opening address directed attention to the desirability of discipline and restraint on the part of the authors of scientific papers. He said there is much scientific literature which need never be produced, and of that which justifies its appearance 80 per cent could be improved by drastic reduction in length and by clear writing. He urged scientists to publish the results of their work once and once only, and not in a multiplicity of guises. He went on to say: "However we improve the raw material of information there will still remain poor papers, unnecessary papers, trivial papers and repetitious papers. What are we to do with them? What is to be stored? Is it the fruit of the tree of knowledge or is it the fallen leaves? For my part I should be happy if the fruit only were preserved, as I cannot conceive of any collecting and storage system adequate to cope with the world's output of scientific information as it grows at present, and I view with only a little compunction the prospect of the loss of minor contributions to knowledge provided that the ripe fruit can be preserved. The few fallen leaves of my own work are already losing their individuality as they dissolve into the rich compost of the background knowledge of the rising generation. Their individuality is lost, but they have contributed a little to the vigour of the pushing young shoots at the top of the tree—and of course I have a fruit or two up my sleeve still. Of course we have the difficulty: Who is to decide what is the fruit and what is the fallen leaf? Can any information service work on an eclectic principle? I think it can. But only with the full co-operation of the user and the maker of information".

As mentioned above, the primary purpose of the Conference was discussion. No attempt was to be made to arrive at conclusions in the form of recommendations. The Conference certainly achieved its objects of exposing the problems of retrieval of information and of bringing the interested parties together. Although each panel was at liberty to deal with its subject in its own way, the general procedure adopted was to assume that the papers had been read; the panel members then commented on the subject, referring to papers as desired, and a period of general discussion followed.

Panel 1 concerned literature and reference needs of scientists. The papers chiefly related to surveys of information requirements of scientists in a variety of different research organizations, and methods by which research workers find information. A fact brought out by the papers was that communication of scientific information is done as much through personal conversation as by reading the literature. It was stated that the volume of scientific literature is doubling every seven years. It was evident that it is impossible to make generalizations in methods of communicating information and that not only do methods vary from subject to subject but also from user to user and according to the uses to which the information is to be put. Studies on the habits of scientists in acquiring information are still imperfect, but may be the bases for action in certain local situations. The present services go a considerable way towards meeting the needs of the competent research worker in his own field, although the use of abstracts seems to be on the decline and the research worker is not so well served when he wishes to explore a field other than that with which he has some familiarity. The importance of the unplanned contact with new scientific information was stressed.

A plea was made for more studies of the physiological nature of recognition and memory. One contributor urged that neurones as well as electronics have a role in the retrieval of information. Reading-rates of students of about equal standard were reported to vary from 2·5 to 9·8 words a second, and further studies on this and the related problem of reading and visual fatigue were suggested as a fruitful field of investigation.

The second Panel discussed the effectiveness of abstracting and indexing services. The discussion reploughed familiar ground in relation to authors' abstracts versus non-author abstracts, informative abstracts versus indicative abstracts, the role of highly centralized general abstracts (as in Moscow) and specialist abstracts (as in the Commonwealth Agricultural Bureaux), and little that was new emerged. One study, however, reported that in spite of all that is said about biasing abstracts for particular classes of readers, there is a growing tendency by many abstracting agencies to use authors' abstracts. There seemed to be a generally favourable opinion that if authors' abstracts are properly edited they can be of considerable service, and the action taken by the Abstracting Board of the International Council of Scientific Unions in encouraging this in physics abstracting was supported. On the other hand, the delays in issuing some abstracts is becoming so great that in rapidly developing subjects they are of little use for current awareness, and alternative means, for example the quick circulation of the titles of papers as in *Current Chemical Papers*, will have to be investigated. The importance of indexing was stressed by Dr. E. J. Crane, of *Chemical Abstracts*, and in commenting on the possible use of mechanical aids in abstracting he warned against the danger of departing from existing high standards in abstracting and indexing.

The third Panel was concerned with the effectiveness of monographs, compendia, and specialized centres. Some time was devoted to discussing reviews, and it was generally agreed that an insufficient number of first-rate people are willing to give time to their compilation for the benefit of a variety of users—the specialist, the specialist in related fields, the teacher and general reader. The suggestion was made that review writing should be a joint effort of a junior who did the searching of the literature and an experienced scientist who would provide the necessary critical judgment. The review should preferably deal with concepts and leave data to special compendia. The writing of monographs seems to be going out of fashion, although it remains important in biology. An experiment in the U.S.S.R. was described where the Institute of Scientific Information plans to issue a series of monographs attempting to cover the whole field of science: the Russian definition of a monograph is a scientific work which concentrates and develops all aspects and facets of a given scientific discipline and requires strict objectivity from the author. The chief difficulty will be the shortage of suitable authors.

Dr. E. Pietsch, director of the Gmelin-Institut, Germany, described in detail the organization of the "Handbuch für der Anorganische Chemie", where the evaluation of the data is by far the most costly operation in preparing the text. The eighth edition will consist of 60,000 pages and will cover two hundred years of the subject up to 1950. If the "International Critical Tables" were to be re-issued on the same lines as twenty-five years ago, it might require several hundred volumes. The issue of abbreviated tables of data in the form of handbooks for specific uses was strongly urged, and a suggestion was made for increased use of directories of scientific workers and their interests to assist the communication of information. There was also some discussion on the increased use of technical reports, only a fraction of which, however, is abstracted in the abstracting journals because the editors of the latter consider the technical report to lack the careful preparation imposed on the writing of a paper for a journal and because a report, or part of it, is liable to be published again as a paper. The need to give greater emphasis to the value of books in information services was stressed.

A variety of national scientific information centres were described; for example, those in the U.S.S.R., India, France, Japan, Czechoslovakia and Poland. A novel feature of a Czechoslovak service is that all inquiries must be made by telephone, as it is thought that only by this means can the inquiry be sufficiently well defined by discussion to make the information service really efficient. The Soviet representative advocated the centralized information centre and quoted Vavilov as saying that "the contemporary man of research is in the same position in relation to the holdings of libraries of the world as the gold prospector faced by the jungle". The centralized institute dealing with national and international scientific literature was adopted in the U.S.S.R. because all knowledge is organically interconnected, and in one institute, where are concentrated specialized personnel, all collective data, etc., knowledge from one field, for example, physics, can be readily related to other fields such as chemistry, biology, metallurgy. In Poland, where there is an information service in applied science, only the central direction is concentrated in Warsaw and a decentralized system, using eighty different regional institutions and a hundred or more industrial centres, is found to be effective in providing an organized person-to-person contact.

Panel 4 considered the organization of information for storage and search, and devoted some time to the comparison of the characteristics of existing systems. It was considered that, at present, each specific problem requires a system tailored to the special demands on it and the need for further experiment was admitted. Where machines have been used, it seems too early to generalize on their merits or demerits, and consideration of the replacement of the human brain by a machine in a system of retrieval only emphasized the need for any machine to have a good master.

Panel 5 discussed the organization of information for storage and retrospective search. There were twenty preprinted articles in this section, many dealing with the classification or coding of information in specialized fields, in such a way as to enable mechanical retrieval. Words were regarded as being too imprecise for large-scale mechanical information retrieval, and it was suggested that a rigorous mathematical theory of systems should be sought for future development. Further study was proposed of language and the nature of communication—a multi-stage process with the interplay of ideas in a highly unorganized state. In the meantime, the solution of narrow practical problems seemed the more profitable line of advance. Even with a high-speed machine of long memory, the intellectual problem of searching the literature will remain. Machines require careful programming, and it was stated that all they can achieve is to do clerical work more quickly.

Panel 6 concerned itself with the possibility of a general theory on the organization of information for storage and retrospective search. This gave rise to a great deal of discussion, and for those who are expert in one or more systems this may well turn out to have been a profitable occasion, for it appeared that no existing theory can be directly applied, and much more experiment, discussion and thought will be necessary before a general theory can be evolved. The greatest difficulty is to provide for the interaction between the inquirer and his information sources ; thus, any general theory must accommodate the learning process and the consequent need to modify itself continuously. It seems likely that, with so much interest in the subject, something constructive may emerge within the next few years.

Panel 7 covered a wide range as it discussed the responsibilities of governments, scientific societies, universities and industry for improved information services and research. The Panel took an early opportunity of pointing out that the only indispensable person in the whole subject is the scientist, and that through his societies he is the principal maker and user of scientific information. Scientific societies should, if possible, be self-supporting in the publication of original work, but any help required in the secondary information services should have government support, as scientific information is a national resource. As a user, the specialist usually organized his own search, and it was suggested that universities might encourage, more than is done at present, young research workers in learning how to use the literature of their subject as well as how to produce it by the better writing of their papers. Scientific societies might encourage authors not only to submit abstracts but also provide key index words to facilitate the editing of abstracts and indexing.

Nowadays some national governments are large-scale users and producers of information and have responsibilities for its proper distribution. This varies from the small country with a relatively recent acquaintance with scientific research, where information services receive their main support from international agencies, for example, from Unesco through a regional office, to large scientifically advanced countries where national funds are provided on a large scale and where government agencies provide a plan for stimulating and supporting scientists and engineers in dealing with information problems. Whatever method is employed, the whole-hearted co-operation of those who produce the information is necessary.

In the international field the work of the Abstracting Board of the International Council of Scientific Unions was cited as a good example of co-ordination of existing services. The Panel was not in favour of trying to establish an international scientific information centre at present, but rather favoured the co-ordination of national services, for example, through national library services. The trend should be towards more national centres and more international co-ordination. A statistical survey of the economics of the various types of national centres would be helpful in this connexion.

There were no formal conclusions of the Conference, but hopes were expressed that some more formal international organization might follow, possibly through national academies of sciences. Whether this happens or not, the participants in this International Conference on Scientific Information were stimulated by attending it, and it will not be surprising if they in turn stimulate further action towards a renewed consideration of the many and growing problems of scientific information services in their respective countries. That those concerned in the United States are active is obvious.

D. C. Martin

OBITUARIES

Sir Hubert Wilkins

The death occurred in New York early in December of Sir Hubert Wilkins ; he was seventy years old. He will be remembered as a pioneer both in arctic and in antarctic travel.

Wilkins first visited the Arctic as second-in-command of Vilhjalmur Stefansson's Canadian Arctic Expedition which went north in 1913. Wilkins remained a member until 1917 and during these years he became expert in travel on arctic pack-ice. He himself, however, was always keener on air travel and was probably the first man to fly in the Antarctic. His flights in the Arctic, after more than one attempt, culminated in 1928 in an adventurous journey from the north of Alaska to Spitsbergen, for which he received the Founder's Medal of the Royal Geographical Society. His arrival in the latter region stirred the people of Great Britain as no other arctic flight had done. He wrote an exciting dispatch describing the journey for *The Times* ; it was one of the best travel reports ever written.

An important feature of Wilkins's explorations was his work as a naturalist. He made collections in Australia ; and he joined Shackleton on the *Quest*, for example, as a collector of natural history specimens. Wilkins was also in the Antarctic with

J. L. Cope in 1921 along with T. W. Bagshaw and M. C. Lester.

One of his most spectacular proposals, however, was his putting forward the idea of taking a submarine under the arctic pack-ice, and by the effort which he made with Lincoln Ellsworth in 1931 he was thus anticipating the successful voyages made by a later *Nautilus* in 1958.

One of Wilkins's earlier associations with Lincoln Ellsworth had led to an important flight across a sector of Antarctica in December 1928. On this occasion a message reached Britain from Wilkins, who was on board ship, that Ellsworth had got into difficulties after reaching the edge of the Ross Barrier together with his pilot, Ben Eielson. This led the British Colonial Office to arrange that the *William Scoresby* should be diverted at short notice to the Antarctic, and Ellsworth and Eielson were picked up without difficulty.

Wilkins, on these flights in December 1928, had stated that Graham Land was insular. This led to much confusion at the time and attempts to identify places in Graham Land such as Stefansson Strait and Crane Channel. The matter was not cleared up until the Rymill Expedition began surveys in 1934. Wilkins had, in fact, regarded as straits what in reality were glaciers. At the time, however, Wilkins's claims to have discovered 'Hearst Land' and 'Stefansson Strait' were a source of controversy.

Hubert Wilkins was one of the earliest explorers of the air age, and his picturesque figure with his short, trim beard made him well known and popular in the United States, where he had made his home.

J. M. Wordie

Prof. Florence A. Mockeridge

Florence Annie Mockeridge, emeritus professor of botany in the University College of Swansea, died on December 18 at the age of sixty-nine.

Florence Mockeridge studied first at Woolwich Polytechnic (Penfold gold medallist) and then at King's College, London, as a Merchant Taylor's Company Scholar. She graduated with first-class honours in the Pass B.Sc. in 1909 and again in the Honours B.Sc. in 1910 and was awarded the Carter Gold Medal of King's College. During 1911–17 she undertook research with Prof. W. B. Bottomley, first as a Layton Research Student and later with grants from the Board of Agriculture and Fisheries. During this period she was engaged upon pioneer studies on nitrogen fixation by *Azotobacter* and on the growth-promoting substances ('auximones') of natural manures. Her published researches in this field led, in 1917, to the award of the D.Sc. (London). During 1917–22 she was successively demonstrator and University lecturer in botany at King's College and, continuing her researches, demonstrated the presence in natural manures of nucleic acid degradation products, including the purine bases, and examined their growth-promoting activities.

In 1922, Dr. Mockeridge was appointed independent lecturer in botany in charge of the Department of Biology of the newly established University College of Swansea. Here, in improvized accommodation and with a very small staff, she built up, over a period of thirty-two years, the reputation of the honours degree in botany and directed the work of a succession of research students. Her outstanding ability as a teacher and her scientific achievements in the face of inadequate facilities and often indifferent health were recognized by her election in 1936 as the first professor of botany in the College. She long pressed for the establishment of separate Departments of Botany and Zoology, and when, shortly before her retirement in 1954, this was to become possible by the decision to erect a new Natural Sciences Building (*Nature*, 179, 124; 1957) she planned the new facilities with great care and wisdom in full knowledge that their use would be for her successors.

Prof. Mockeridge also played a big part in the development of the University College, being dean of the faculty of science during 1933–35 and again during 1941–43, vice-principal during 1949–51 and, for many years, treasurer of the Student's Representative Council. She took a deep personal interest in the welfare and continuing progress of her students, whose affection and respect for her were recently expressed by their presentation to the Department of Botany of her portrait in oils.

She was always much sought after as a lecturer all over South Wales. For many years she was editor of the *Proceedings of the Swansea Field Naturalists' Society*. On her retirement she became chairman of the Science Committee of the National Museum of Wales and a member of the Glantawe Hospitals Management Committee.

H. E. Street

Sir Ralph Pearson, C.I.E.

Ralph Sneyd Pearson, who died on December 8, aged eighty-four, was educated at the Royal Indian Engineering College, Coopers Hill, and joined the Indian Forest Service in 1898.

After service as a territorial forest officer in the Bombay province, he was posted to the Forest Research Institute, Dehra Dun, to take charge of the recently formed Economic Branch in 1909. Until 1920 he had to work largely single-handed, devoting special attention to the adoption by the railways of antiseptically treated sleepers to relieve the heavy demands on the supply of naturally durable timbers. He also surveyed the possibility of using bamboo for paper-making on a commercial scale.

In 1920 the Economic Branch was much enlarged by the formation of several sections dealing with special aspects of the utilization of forest products, and Pearson was sent to Canada and the United States to recruit specialists to take charge of some of them. It was then that the results of the work he had done before and during the First World War began to gain the general acceptance they have since received with great benefit to Indian industry.

In 1925 he retired from the Indian Forest Service and returned to Britain, where he was appointed director of the new Forest Products Research Laboratory (Department of Scientific and Industrial Research), which he built up very much on the lines of his branch at Dehra Dun. There he remained until 1933, when he had to retire for reasons of health.

He was made C.I.E. in 1920 and was knighted in 1933; he received the honorary degree of LL.D. of the University of St. Andrews.

The author of several monographs on various forest products, his chief work was "The Commercial Timbers of India", written in collaboration with the late H. R. Brown, of the New York State College of Forestry. He was a good shot and a very keen cricketer who was always very popular with his staff.

He married Constance Ommaney, who died in 1938, and he is survived by two sons and a daughter.

W. A. Robertson

NEWS and VIEWS

Physical Biochemistry at Canberra : Prof. A. G. Ogston, F.R.S.

DR. A. G. OGSTON has been appointed to the chair of physical biochemistry in the Australian National University at Canberra. This is a new establishment, and his Department will be housed in the John Curtin Institute for Medical Research, where Prof. A. H. Ennor holds the chair of biochemistry. Dr. Ogston took a first-class degree in chemistry at Oxford in 1933. Later, in 1938, he took a degree in physiology and was appointed Oliver Gatty Fellow and Tutor in Biological Sciences at Balliol College. In addition to his college fellowship he holds the appointment of reader in biochemistry in the University of Oxford. His teaching and research have been characterized by an unusually clear understanding of both the physical and biological approaches and their relation to one another. His recent work has been concerned mainly with the properties of hyaluronic acid and its isolation from synovial fluid. Since 1955 he has been chairman of the editorial board of the *Biochemical Journal*. The formation of a department devoted to physical biochemistry in Canberra will be important, not only for the work it produces but also for the stimulus it provides ; the Australian National University is to be congratulated in attracting a scientist of such distinction. Dr. Ogston will take up the appointment in 1960.

Chemistry at Edinburgh : Prof. J. P. Kendall, F.R.S.

JAMES PICKERING KENDALL, who is retiring from the chair of chemistry in the University of Edinburgh at the end of the present academic year, succeeded Sir James Walker in that chair in 1928, the appointment following an extensive experience of university teaching, research and administration as professor of chemistry in Columbia University, New York (1913–26), and in New York University (1926–28). His graduation in Edinburgh as M.A., B.Sc. in 1910 was followed by his association with Arrhenius and other continental workers in the earlier work on solutions, leading to his active research interest in general solution chemistry, with particular reference to ionic migration. The course of this work was accompanied by the publication of an extensive series of articles and text-books, particularly the Smith–Kendall series of college chemistries, and including "At Home among the Atoms" (1929), "Breathe Freely" (1938), "Young Chemists and Great Discoveries" (1939), and "Humphry Davy" (1954). He was elected a Fellow of the Royal Society in 1927.

During the past thirty years Prof. Kendall has taken a full share of Senatus and Faculty business—he is at present Dean of the Faculty of Science—and has served as a member of the University Court and of many of its committees. His tenure of the chair has been marked by many changes in the Department of Chemistry, particularly during the post-war period. These have included the institution of the Forbes chair of organic chemistry, to which Prof. E. L. Hirst was appointed in 1947, the enlargement and rebuilding of the Department and extensive developments in teaching and research. Prof. Kendall has for many years taken a great interest in the work of the Royal Society of Edinburgh, being in turn member of Council, secretary for meetings and general secretary, a post he occupied during 1939–49. During 1949–54 he served with distinction as president of the Society.

Dr. T. L. Cottrell

DR. TOM LEADBETTER COTTRELL, who has been appointed to succeed Prof. James Kendall, received his early education at George Watson's Boys' College, Edinburgh. After entering the University of Edinburgh, he specialized in chemistry and graduated B.Sc. in 1943 with first-class honours. He then took a post in the Research Department of the Explosives Division of Imperial Chemical Industries, Ltd., where he developed his interest in physical chemistry. In 1946 he was seconded for special work in the Physical Chemistry Laboratory of the University of Oxford. Shortly after his return to Ardeer he was appointed head of the Physical Chemistry Research Section of the Nobel Division of Imperial Chemical Industries, Ltd. His contributions to the solution of fundamental problems in physical chemistry, with particular reference to chemical kinetics, thermochemistry and intermolecular forces, were of such outstanding merit that he was awarded in 1952 the Meldola Medal of the Royal Institute of Chemistry. Two years later he published a book on "The Strengths of Chemical Bonds", the second edition of which was called for after an interval of only four years. In 1958 he was awarded the D.Sc. degree of the University of Edinburgh for his achievements in physical chemistry. After a wide experience of both fundamental and applied research work at Ardeer, Dr. Cottrell was transferred in 1958 to the directorate staff of Imperial Chemical Industries, Ltd., at its London headquarters, where he acted as personal assistant to Sir Ewart Smith, deputy chairman of the Company. In returning to Edinburgh at the age of thirty-five, Dr. Cottrell will become a professor in the department in which his father previously held the post of lecturer in technical chemistry.

Royal Astronomical Society Awards

THE Royal Astronomical Society has recently made the following awards : the Gold Medal of the Society to Dr. R. A. Lyttleton, lecturer in mathematics in the University of Cambridge, for his outstanding contributions to many branches of theoretical astronomy, in particular to the problems of the stability of rotating fluid masses, of the constitution of the stars and stellar evolution, and of the origin and peculiarities of the solar system ; and the Eddington Medal to Dr. J. S. Hey, of the Royal Radar Establishment, Malvern, for his outstanding discoveries concerning radio emission from the active Sun, radio reflexions from meteors, and discrete sources of cosmic radio emission.

Gold Medals of the Institut Francais des Combustibles et de l'Energie

GOLD medals, designed to recognize outstanding achievement in the field of utilization of fuel and power, were recently presented in Paris to six fuel technologists of international reputation. The medals were a new foundation of the Institut Français des

Combustibles et de l'Énergie, and the presentations were made by M. Ramonet, the then Minister of Industry and Commerce. The recipients were Dr. D. T. A. Townend, director-general of the British Coal Utilization Research Association; Prof. W. H. McAdams, Massachusetts Institute of Technology; M. G. Darrieus and Prof. G. Ribaud, members of the Academy of Sciences, Paris; Dr. F. Münzinger, German Federal Republic; and Signor F. Squassi, presidente della Sezione Latium dell'Associazione Termotecnica Italiana.

A Large Sunspot Group

THE large sunspot group which has recently attracted some attention appeared around the Sun's limb in heliographic latitude 12° N. on January 4. It was carried across the disk by the Sun's rotation about its own axis, and disappears at the western limb on January 17. A close bipolar structure, the group has somewhat diminished in area since January 8, when its area was 3,000 millionths of the Sun's visible hemisphere. It is, however, the largest group observed since May 1951 and, consequently, of the present sunspot cycle. Although there has been an unprecedented number of spots during the recent peak activity, no group has been observed approaching in size that seen in April 1947, the maximum area of which reached 6,100 millionths of the Sun's visible hemisphere and was the largest recorded since the Greenwich observations began in 1874. Adverse weather conditions at Herstmonceux have prevented continuous watch on this group, but so far (until January 11) no associated flare activity has been observed.

Central Advisory Water Committee

THE Central Advisory Water Committee recently held its fourth meeting in London at the Ministry of Housing and Local Government, under the chairmanship of the Minister, Mr. Henry Brooke, when it received and adopted reports from two sub-committees set up in 1955 to inquire, respectively, into the growing demand for water and into the collection of information about water resources. Both reports will be published shortly.

The Committee requested the sub-committee on the demand for water to undertake a further inquiry, with extended terms of reference as follows: "In connexion with their investigations into the extent to which demands for water are increasing and the problems involved in meeting those demands, to inquire into the extent of uncontrolled abstractions of surface water for agriculture, especially irrigation, for industry and for other purposes, and into the effect of such abstractions on the quantity and quality of surface water available for all purposes; to consider whether powers are needed to control such abstractions in general or in particular; and to make recommendations". Prof. J. Proudman was appointed chairman of the sub-committee in succession to Alderman Yates, who has resigned from the chairmanship owing to pressure of other work.

Zoological Society of London: Young Zoologists Club

ALTHOUGH the Zoological Society of London has been in existence for more than a hundred years, it has never had a junior section through which the great amount of scientific knowledge at its disposal could be made available to school-children. About a year ago it instituted, with the co-operation of the educational authorities of the Greater London area, regular lecture-demonstrations for school-children. The Society is now launching a Young Zoologists Club (XYZ Club) for children between the ages of eleven and eighteen. The Club will be based on the London Zoo. For 10*s*. a year (there are, as well, reduced subscription rates for schools, clubs and natural history societies) the membership includes the Club badge, free admission tickets (to the London Zoo, including the Aquarium and Children's Zoo, and Whipsnade Park), competitions with substantial cash prizes, meetings, an Information Bureau and, above all, the *Zoo Magazine*, which for the present is being published three times a year. Further information can be obtained from XYZ Club, The London Zoo, Regent's Park, London, N.W.1.

Geochemistry

As a means of making available to all interested individuals some of the current Russian research in geochemistry, the Geochemical Society of the United States has undertaken to publish an English translation of the Russian journal *Geokhimiya*, published by the Academy of Sciences of the U.S.S.R. The first number of this translation has now appeared (*Geochemistry*, No. 1, 1958. (A translation of the journal of the Academy of Sciences, U.S.S.R.) Pp. 1–130. Subscription (for eight issues) 20 dollars a year. Ann Arbor, Michigan: Geochemical Society, Prof. E. Wm. Heinrich, Mineralogical Laboratory, The University, 1958). It contains research papers dealing with the ionium method of determining the age of marine sediments, the formation of free hydrogen in the Earth's crust, X-ray investigations of natural oxides of uranium, paragenesis in boron-bearing magnesium skarns, the evolution of rocks during progressive metamorphism, the distribution of cobalt, nickel and copper in hydrothermally altered rocks, experimental studies of the oxidation of cobalt and nickel arsenides in solutions containing oxygen and carbonic acid, rhenium in molybdenites, the zirconium/hafnium ratio in zircons, and a contribution to the geochemistry of titanium in intrusive processes of granitic series. The translation concludes with a brief description of the recent International Conference on Interplanetary Science.

Symposium on Peptide Synthesis

AN International Symposium was held in Prague during September 8–15, when chemists from many countries in Europe met, at the invitation of the Czechoslovak Academy of Science, to discuss the synthesis of peptides. The primary object of the symposium was to exchange experience in this field rather than to communicate new work (although several of the contributions included unpublished work), and as a basis for each section of the discussion reviews were contributed by Prof. T. Wieland (Frankfurt) on peptide bond formation based on carboxyl activation; Prof. S. Goldschmidt (Technische Hochschule, Munich) on peptide bond formation based on amino-group activation; Dr. G. T. Young (Oxford) on racemization in peptide synthesis; Dr. E. Wünsch (Max Planck Institut, Munich) on amino-group protection; Prof. E. Taschner (Danzig) on carboxyl group protection; Dr. J. Rudinger (Prague) on peptides of the diamino and dicarboxylic acids; Prof. M. Brenner (Basle) on peptides of the hydroxy-amino-acids; Dr. Young on peptides containing cysteine; Prof. M. M. Shemyakin (Moscow) on peptides of α-substituted α-amino-acids; and Dr. M. Rothe (Berlin) on the synthesis of cyclic peptides. A paper on the synthesis of optically active peptides from racemic amino-esters, by Prof. M. M. Botvinik (Moscow), was read in her absence. The proceedings, with the discussion, are to be published in a special issue of the *Collection of Czechoslovak Chemical Communications*. It was generally agreed that the meeting had been most rewarding, and that an attempt should be made to gather regularly in this fashion.

World Low Air Temperature Record

THE world low air temperature record of – 102·1° F. at the South Pole on September 18, 1957 (*Nature*, 181, 1109; 1958), was exceeded in the polar night of 1958 at the Russian International Geophysical Year Antarctic stations Sovetskaya (78° 24′ S., 87° 35′ E., elevation about 3,700 m.) and Vostok (78° 27′ S., 106° 52′ E., about 3,500 m.) The Sovetskaya station recorded – 86·7° C. (– 124·1° F.) between 1900 and 2000 L.M.T. on August 9. The measurement was made with a distant-reading electrical-resistance thermometer of known correction. The temperature is stated to have been lower immediately afterwards but there was no calibration for the thermometer. Other readings nearly as low at these stations were:

Vostok:	– 80·7° C.	(– 113·3° F.)	on June 15
	– 85·8° C.	(– 122·4° F.)	on August 8
Sovetskaya:	– 81° C.	(– 113·8° F.)	on June 19
	– 83° C.	(– 117·4° F.)	on June 25

The extremes in June occurred in periods of light winds and clear or nearly clear sky, which is the weather most favourable for very low temperatures. No information is available about the weather at the time of the August readings. The values were stated in reports from the American meteorologist, Mr. Morton Rubin, at the Russian base at Mirny, published in the *Monthly Weather Review* of the U.S. Weather Bureau.

Oystercatchers and Mussels

R. E. DRINNAN, of the Fisheries Research Board of Canada and formerly of the Fisheries Experiment Station, Conway, has described the feeding of the oystercatcher (*Haematopus ostralegus*) on the edible mussel (*Mytilus edulis*) in the estuary of the River Conway, Caernarvonshire, during the winter 1955–56 (Ministry of Agriculture, Fisheries and Food Fishery Investigation, Ser. 2, 22, No. 4). Feeding was studied on the mussel beds at the mouth of the River (Morfa) and in an area higher up the estuary above the suspension bridge (Pensarn). The oystercatcher populations of these areas are discrete. The birds are present between August and late March and are probably British breeding birds. Feeding follows the tidal cycle, continuing throughout the period when mussels are uncovered, high water periods being spent in non-feeding roosting flocks. This cycle continues during darkness. Quantitative data on food intake for the daylight feeding period show that each bird eats about its own weight of wet mussels a day. No precise measure of the effect of oystercatcher predation on the mussel population was made; but, at the Morfa, population samples through the winter showed the steady removal of the larger size groups by the birds. The present work is compared with previous results obtained by Dewar in the Firth of Forth and many divergences noted. These can all be ascribed to differences in feeding behaviour of the birds in the two studies.

Harwell Reactor School Courses

A SECOND course on the Control and Instrumentation of Reactors will be given at the Harwell Reactor School, Berkshire, during July 7–17, and will be open to British and overseas students. The topics to be treated will include: revision of elementary reactor kinetics, control and instrumentation; automatic control of reactors and nuclear power plants; application of computers; reactor transfer functions and function analysers; neutron flux scanning; radiation detectors and their siting in reactors; reactor safety circuits; conventional instrumentation; use of transistors in reactor instrumentation; burst slug detection; spatial instabilities in reactors; and data-reduction problems on large reactors. In addition to the lectures, there will be visits to zero-energy and high-flux research reactors and other relevant parts of the Atomic Energy Research Establishment. The fee for the course will be 50 guineas, exclusive of accommodation, and application forms, available from the Reactor School, must be returned by May 7 to the Principal.

United States Atomic Energy Commission Training Courses

THE U.S. Atomic Energy Commission has established a training programme at the Shippingport Atomic Power Station for supervisory personnel of domestic and foreign organizations engaged in or planning the design, construction or operation of nuclear power plants. The training programme is being conducted at the Shippingport Atomic Power Station, Pa., a joint project of the Commission and the Duquesne Light Co., because it is the only large-scale nuclear electric power plant at present in operation in the United States. It will be conducted by the Duquesne Light Co. for the Commission, and will enrol twenty-five participants every three months for a six-month training course, which will include lectures and practical plant work. The courses, the first of which started on January 5, are designed to acquaint the participants with the operation of the Shippingport plant and to provide operational training within the plant. The tuition charge is 2,000 dollars to cover associated operating costs.

University News: Birmingham

THE Council of the University of Birmingham has received from the firm of Joseph Lucas, Ltd., a gift of £100,000, to be used for building a hall of residence for graduate students in engineering.

The title of reader in experimental pathology has been conferred on Dr. K. W. Walton, senior lecturer in experimental pathology, and that of reader in mathematical economics on Dr. F. H. Hahn, senior lecturer in economics. The following appointments have also been made: Dr. D. B. Idle, to be lecturer in botany; Dr. B. John, to be lecturer in cytology in the Department of Genetics; Dr. R. G. O. Kekwick, to be lecturer in malting and brewing and applied biochemistry.

Leeds

MR. J. TRENAMAN has been appointed to the Granada Television Research Fellowship, endowed by Granada TV Network, Ltd., in the University of Leeds, for a minimum period of five years, with provision for the necessary staff and services. The purpose of the Fellowship is to undertake research into the impact of television over as wide an area of inquiry as practicable in the fields of entertainment, politics, information and public affairs—and into its influence on public tastes, habits and outlook. Mr. Trenaman read English at King's College, London, and later graduated B.Litt. in the University of Oxford. In 1945 he was appointed head of analysis in the B.B.C. Audience Research Department, and in 1948 became research officer to the B.B.C. Further Education Experiment exploring the use of broadcasting as a medium of education. He has since held the post of further education liaison officer to the B.B.C.

"Fuel and Power in British Industry"

MR. A. M. WANDLESS, of the Scientific Department, National Coal Board, writes: "In the article under this title which appeared in *Nature* of December 20, I am reported as having stated in my address to the Manchester Joint Research Council's Symposium on Fuel and Power that the workable reserves of coal in Britain are of the order of 1,000 million tons. This, of course, is an absurdly low figure. In dealing with the difficult and necessarily uncertain business of attempting to predict workable or economic reserves of coal, I said that figures as low as 44,000 million tons (that is, 200 years life at the present rate of extraction) had been computed, but that this estimate was almost certainly too low. I suggested an upper ceiling of 100,000 million tons, but I pointed out that it all depends how much we are going to need coal in the future, and what we are prepared to pay for it. There is probably something of the order of 170,000 million tons lying in the ground in seams more than 1 ft. in thickness".

Birds and Mammals of Canada

REFERENCE was made in *Nature* of November 15, p. 1347, to two recent publications from the National Museum of Canada, namely, "Quelques Oiseaux du Canada" and "Canadian Mammals". We are informed that the first of these is available also in English under the title "Some Canadian Birds", this being the original version. The price is the same as that of the French edition, 35 cents.

Announcements

AN honorary degree of doctor of technical science was conferred on Sir John Cockcroft by the Technical University of Delft on January 10.

PROF. J. M. YOFFEY, professor of anatomy in the University of Bristol, has been appointed Knight first class of the Order of the Dannebrog for his services to the Medical Schools of the Universities of Copenhagen and Aarhus.

MR. GUSTAVUS GREEN, known for his work on the design and development of the early Green aero-engines, has been made an honorary companion of the Royal Aeronautical Society; Mr. Green was born in 1865 and designed the 60-h.p. engine used in a Short No. 2 biplane flown in 1909.

SIR RUSSELL BRAIN, president during 1950–57 of the Royal College of Physicians, will give the Eddington Memorial Lecture for 1959 in Cambridge, at the Arts School Lecture Theatre, Bene't Street, on February 24, at 5 p.m. The title of the lecture will be "Science, Philosophy and Religion".

THE Czechoslovakian Academy of Sciences and the Purkyne Medical Society have arranged a symposium on antibiotics, to be held in Prague during May 18–23. The symposium will be divided into three sections on: problems of the biosynthesis of antibiotics; the scientific pathophysiological basis of antibiotic therapy; and the problems of fermentation engineering and the non-medical uses of antibiotics. Summaries of papers covering new and unpublished results, to be read in English, German, Russian or Czech, should be received by the secretary, Dr. M. Hermansky, Antibiotics Research Institute, Rostoky, near Prague, not later than February 15.

THE third conference on Electronic Digital Computers and their Industrial Applications will be held in the Department of Mathematics, College of Technology, Birmingham, on February 25, when members of the English Electric Co. will deliver talks on the installation, operation and maintenance of digital computers; programming strategy and techniques, including automatic programming; engineering and scientific problems; the use of a computer system in commercial organization; and the mortgage problem. Applications can be made to the Registrar, College of Technology, Gosta Green, Birmingham 4.

AN international symposium under the auspices of the Centro per la Vaccinazione Antitubercolare of the Istituto d'Igiene dell'Universita di Pisa, devoted to the topic of vaccination against tuberculosis with non-living vaccines, will be held in Florence during April 5–7. The organization of the meeting has been undertaken by the director of the Centre, Prof. Giulio Buonomini, from whom further information can be obtained. The symposium is intended to provide an opportunity for the exchange of information, experiences and ideas by investigators actively engaged in attempts to produce a safe and effective non-living vaccine against tuberculosis. To assure a maximum degree of informality and freedom of discussion, participation in the symposium has been limited to about twenty invited workers.

THE National Academy of Sciences with the joint sponsorship of the National Science Foundation, the Office of Naval Research and the Air Force Office of Scientific Research has arranged an international seminar on "The Atomic Mechanisms of Fracture", to be held at the New Ocean House, Swampscott, Massachusetts, during April 12–14. The central theme of the conference is the basic atomic mechanism by which fracture occurs in metals, ceramics and polymers; emphasis is placed on fundamental studies of the basic mechanisms of cleavage and of ductile, fatigue and high-temperature fractures. The programme will consist of a series of invited papers, which will be circulated in advance. Further information and forms of application can be obtained from Prof. B. L. Averbach, chairman, or Dr. D. K. Felbeck, secretary, Conference on Fracture, National Academy of Sciences, 2101 Constitution Avenue, Washington 25, D.C.

MR. W. A. FERGUSON, who has been appointed secretary of the British Museum (Natural History), is at present in the Director's office, British Museum (Bloomsbury), and not at South Kensington, as stated in *Nature* of January 3, p. 18.

SCIENTIFIC RESEARCH IN AUSTRALIA

THE ninth annual report of the Commonwealth of Australia Scientific and Industrial Research Organization* covers the year 1956–57, in which expenditure was £6,575,255. Of this, £935,830 was expended on investigations financed from the Wool Research Trust Account, which under the new Wool Research Act should now have an income of about £1,700,000. Some new arrangements were made with the universities, including the establishment with the New England University, Armidale, of a laboratory to be used jointly by the University's Faculty of Rural Science and the Organization's Regional Pastoral Laboratory, Armidale; and, with the University of Melbourne, of a joint Engineering Research Station for the study of soil mechanics. Two main research projects relating to water supplies have developed with great promise. The Division of Radiophysics full-scale field trial of artificial rain-making over the Snowy Mountains over two winters promises an increase in rainfall over the target area, and the Mansfield process using cetyl alcohol, developed in the Division of Industrial Chemistry, is now finding application in reducing evaporation from small farm dams and, in modified form, is effective in large reservoirs.

Special reference is made to the completion by the Cattle Tick Research Review Committee of its survey of research within its field. The Committee recommended completion of the ecological background and field tests of pasturing and strategic dipping; studies of tick fevers to assess the consequences of efficient control of ticks; toxicological investigations, especially completion of the work on DDT; and the study of resistance to tick in cattle. The investigations to establish the genetic factors which enable cattle to withstand tropical conditions have indicated that the rate of sweating of zebu cross-breds is not necessarily higher than the average of British breeds, and their ability to withstand heat is thus related to other factors.

In soils research special effort has been directed to the preparation of a new soils map of Australia, and it is hoped to complete the whole project by 1960. In soil chemistry a start has been made on the study of the geochemistry of the three main groups of soils developed on dolerite in Tasmania. In soil physics an equation has been derived for the relation between permeability and the size-distribution of the pores in isotropic porous material, and recently the Division has included soil-stabilization projects in its programme.

The development of the Tobacco Research Institute at Mareeba has progressed and work commenced on tobacco culture, while at Canberra blue-mould disease is being investigated. The investigations into the possibility of establishing safflower as an oil crop in Australia have been concluded. Varieties giving economic yields of oil of high quality have been developed, and the returns per acre were equal to those from wheat in areas suited to the crop. Broad-scale ecological surveys were carried out in the under-developed arid and semi-arid regions of the continent to assess their potential land-use and to investigate problems of agricultural and pastoral development. In work with skeleton weed in cereal crops, selective weed-killers applied before sowing wheat or in the early seedling stage of oats have given marked increases in the yield of grain, due to an increase in the nitrogen available to the crop, while improvement programmes with cattle pastures have enabled cattle in the spear grass region to be marketed one year earlier than is possible from native pastures; in the coastal lowlands sheep and cattle can now be wholly maintained on sown pastures; and in the brigalow country introduced grass and legume species have given highly promising results. Indolyl-3-acetic acid increased the growth of both the veins and petioles of leaves according to a similar pattern, and work has commenced on the recognition of factors which may control leaf-blade (laminar) growth. A study has been made of the ultra-violet spectra and acid-strength of some chlorinated phenoxyacetic acids and their phosphonous and phosphonic acid analogues. Reconnaissance of the east Australian rain-forests was complete, while work in the Murrumbidgee Irrigation Area indicated that impedance to the flow of water in farm ditches due to inflorescences of *Paspalum dilatatum* can be removed by spraying with maleic hydrazide.

Biophysical research supported at the University of Tasmania includes the development of micro-electrode techniques to measure potential differences between points in the cytoplasm of large plant cells such as *Nitella* and *Chara*, further studies of the steady electric field pattern around plant roots growing in solutions of various ionic compositions and concentrations, and studies of the nature of transient changes in the electric field of bean roots following stimulation.

The Plant Fibre Section is developing methods of chemical analysis for examining the changes associated with the conservation and storage of fodder both as hay and silage, and the research programme of the Division of Animal Health and Husbandry continued to place emphasis on contagious pleuro-pneumonia of cattle, infectious forms of infertility and worm parasites, besides the tick research already noted. Good progress is reported with the major production problems with cattle, but—with the greatly reduced significance of the sheep blowfly and other external parasites of sheep through increased knowledge of diseases of sheep and the advent of modern insecticides—research on sheep has been greatly reduced. Nevertheless, foot rot and foot abscess, mycotic dermatitis and worm parasites continue to occupy an important place in the Division's research programme.

Insect ecology and physiology have continued to be the two principal research themes of the Division of Entomology, but besides the developing emphasis on cattle-tick research, the biological control of weeds and the Queensland fruit-fly are increasingly important. Work on the biological control of Noogoora burr was initiated, and the nature of insect resistance to insecticides was further studied in several strains of house-fly. The Wildlife Survey Section concluded its investigations of the marsupials of New South Wales and continued its work on rabbit myxomatosis, while the Division of Fisheries and Oceanography is investigating the interaction between sunlight and chlorophyll in marine plants to enable carbon dioxide in the water to be converted into plant and animal tissue. The Division of Food Preservation and Transport continued to investigate the reaction products in browned freeze-dried apricots and peaches and completed the identification of the cationic constituents, and in a series of studies parallel with those on the 'tenderizing' of beef examined the breakdown of nucleotides in the muscle tissue. Much effort was made to improve methods for killing fruit-fly in harvested fruits, and studies designed to determine the effect of different amounts of initial oxygen in the head space of highly corrosive canned products were continued with test packs of blackcurrants in syrup.

---

* Commonwealth of Australia. Ninth Annual Report of the Commonwealth Scientific and Industrial Research Organization for the year 1956–57. Pp. 179. (Canberra: Government Printer, 1958.) 10*s*. 6*d*.

An extensive programme of research has been undertaken to improve the use of wool as a textile fibre, using increased knowledge and understanding of the complex structure of the wool fibre and its physical and chemical properties to improve it as a textile fibre. Much attention has been directed to simplifying the conventional techniques of worsted processing, and investigations continued on the treatment of woven fabrics with casein, with the object of devising an inexpensive method of shrink-proofing using aqueous solutions. Besides studies on the extension of wool fibres and their setting at new lengths, either temporarily or permanently, research on the degradation of cellulose by fungal enzymes has been diverted from the problem of protecting tent canvas against attack by moulds and linked with research on the digestibility of pasture plants by sheep. The study of the constituents of wool-wax is now concerned chiefly with the long-chain acids of the wax and with lanosterol.

Besides the Mansfield process already noted, an outstanding success of the work of the Division of Industrial Chemistry has been the zirconium–hafnium separation process resulting from its study of the chemistry of Australia's beach sands. Work on the industrial extraction of germanium from the flue dusts of coal-burning power stations continued. Crystallographic studies were directed to the chalcogenide systems of thorium with sulphur, selenium and tellurium. A novel method was evolved of increasing the resistance of concrete products to attack by sulphate solutions. Work was commenced on some aspects of fighting bush fires, the nucleation of clouds, and the separation of the components of tar from the Lurgi process for gasifying brown coal. The theoretical and experimental study of defects in crystals and of their implications in determining the physical and chemical properties of solids continued, as well as the search for alkaloids of possible pharmaceutical value from the native flora, a study of root exudates and their possible significance to agriculture, and the examination of plants known or suspected to be poisonous to live-stock. Considerable progress is reported in basic studies of the chemical reactions of importance in the pressure gasification of brown coal.

The Division of Tribophysics reports major advances in the knowledge of distortions in metals produced by plastic deformation and of topology and reactivity of metal surfaces, and it appears that grain-size is important in controlling both the plastic properties of copper and its annealing characteristics. Demands on the services of the Division of Metrology are increasing, and the electrolytic condensation hygrometer developed by the Division of Physics has fulfilled its early promise, and studies of the basic physics of the crystal surface were made. Research work at very low temperatures was extended to include studies of paramagnetic resonance, and work is in progress to determine the gyromagnetic ratio of the proton. In dielectrics research the emphasis was chiefly on the effect of crystal imperfections on the dielectric properties of solids, but some work continued on liquids, and a theoretical investigation was made of problems related to superconductivity in metals.

The Division of Radiophysics is investigating the basic physical properties of semiconducting materials, and the Organization is undertaking basic studies of the physics of the atmosphere with the view of obtaining a more fundamental knowledge of the weather and the processes which control it. These include further intensive field work in the 'cool change' project, in addition to the Snowy Mountains project already noted, and towards the end of June 1957 emergency operations were commenced in an attempt to induce the maximum possible precipitation from any suitable cloud formations over general areas of the eastern States where drought conditions were beginning to be experienced. In radio astronomy, two large Mills cross-aerials were completed for the study of radio waves from beyond the solar system, and a long programme of observations of the southern part of the Milky Way at a wave-length of 21 cm. yielded interesting results on the general structure of the Galaxy. A new crossed-grating interferometer, designed for high-resolution observations of the Sun, was completed and is in operation. Lists of staff and personnel of the council and committees of the Organization and of published papers are included in the report.

FINANCE OF SCIENTIFIC RESEARCH IN BRITAIN

IN opening an adjournment debate in the House of Commons on December 18 on Government aid to science in Britain, Mr. F. Willey urged the need for more wholehearted support for fundamental research and a bolder approach to science such as characterizes the National Science Foundation in the United States. He suggested that the main responsibility for fundamental research must rest with the Government, but that much other scientific research requires Government assistance in some form and that industry must be persuaded to devote more resources to research. Referring more particularly to the Department of Scientific and Industrial Research, he suggested that the appointment of a full-time chairman to the Council should be considered, and that the status and authority of the Department should be increased. Mr. Willey was disturbed about the disbandment of the Microbiological Group at the National Chemical Laboratory. Nevertheless, he paid a tribute to the work of the present Lord President of the Council, which was endorsed by Mr. R. Fort, who, while in general supporting Mr. Willey's views, argued that fundamental research should properly be the responsibility of the universities. Like Mr. Willey, he echoed some criticism of the British national organization of research which has been recently voiced in *Nature*, but thought that the four research councils provided a good mechanism for determining research priorities and that this pattern could be more widely applied.

In his reply for the Government, Mr. H. Nicholls, Parliamentary Secretary to the Ministry of Works, after reviewing briefly the general pattern of Government support for civil science, pointed out that in the past two years the expenditure of the Department of Scientific and Industrial Research has increased by 23 per cent, of the Medical Research Council by 34 per cent, of the Agricultural Research Council by 20 per cent, and of the Nature Conservancy by 25 per cent. He then announced that the Government has decided to repeat the experiment of financing the Department of Scientific and Industrial Research on a five-year basis. In the first quinquennium ending on March 31, 1959, total expenditure would be about £36 million; for the next quinquennium a total of £61 million is envisaged, reaching £14 million for 1967–68, excluding the contribution to the European Organization for Nuclear Research. Paying tribute to the work of the research associations, Mr. Nicholls said that the thirty-nine research associations and ten smaller organizations in the scheme employ a staff of 4,500, of whom 1,500 are of graduate status, and the 20,000 member firms cover about 50 per cent of manufacturing industry. To their expenditure of about £7 million in 1957–58 the Department of Scientific and Industrial Research contributed about £1·75 million in grants, and for the next quinquennium this will be increased to more than £2 million.

In regard to the universities, Mr. Nicholls agreed that we should look to them mainly for fundamental research and he stressed the value of the increase of postgraduate awards by about 10 per cent in the next five years. By 1963–64, 3,800 students will be receiving grants for training and research from the Department of Scientific and Industrial Research compared with 1,900 this year, and the amount available for research in universities and similar institutions will also be increased three-fold or four-fold in the next five years. In the current year university building projects to the value of £12 million are being started; for the years 1960–63 this will rise to £15 million a year, and technical college building projects to the value of £15 million a year had been in hand since the end of 1956. He had every reason to believe that the target output of 20,000 scientists and engineers a year set for the late 1960's will be achieved.

In conclusion, Mr. Nicholls said that he understood the decision of the Council for Scientific and Industrial Research with regard to the Microbiological Group at the National Chemical Laboratory was taken entirely on scientific merits and without any Ministerial intervention, which would have been entirely contrary to the spirit of the Act. The Lord President was satisfied that the Council had given extremely careful thought to the matter before giving its decision. Mr. John Hynd later referred to the outstanding £130,000 in the capital cost of constructing the Jodrell Bank radio telescope. Mr. Nicholls, in reply, pointed out that the House itself had welcomed the assurance that no voted money should be spent on covering this outstanding item. Later, in a written answer, he added that the Department of Scientific and Industrial Research had already provided £350,000 towards the cost of construction, and had funds at its disposal for financing research of special timeliness and promise. Any applications from the University of Manchester for grants for future research involving the use of the radio telescope would be considered on their merits, and one such grant of £15,200 had recently been offered.

A RADAR SIMULATOR SYSTEM

DURING the Second World War the training of Royal Air Force radar operators was greatly facilitated by the use of apparatus which enabled aircraft echoes to be simulated on the screen of the cathode-ray oscillograph in the radar receiver. Much ingenuity was applied to devising techniques whereby such artificial echoes could be produced and applied to the radar in such a way as to simulate the movement of a real target. By the use of the training equipment which resulted, the need to produce real echoes by flying aircraft was obviated, with consequent savings in fuel, wear and tear of aircraft and elimination of the difficulties of organization and administration.

From these war-time beginnings subsequent development of radar trainers has been considerable, as was shown by the demonstration recently given at the Farnborough works of Solartron Electronic Group, Ltd., of an elaborate installation for simulating air defence exercises and providing realistic instruction in the radar control of the interception of bomber aircraft by fighters. The equipment has been developed under the auspices of the North Atlantic Treaty Organization for use by the Italian Army.

The installation includes seven desk consoles each containing circuits for generating pulses which, when applied to the display oscillograph of a radar receiver, appear as normal aircraft echoes. Each console can simulate two aircraft. Means are provided in the consoles for moving an 'aircraft' along any desired track at speeds which may be varied between its stalling and maximum speeds. Controls are also provided for rate of turn and rate of climb, again in accordance with the capabilities of the aircraft being simulated.

All 'echoes' are displayed on a central plan position indicator from which the general state of the exercise may be studied.

The echo signals, which may be designated as originating from friendly or enemy aircraft as desired, are also displayed on the plan position indicators of a radar receiver. In so doing, the apparatus takes into account the horizontal and vertical radiation patterns, including side lobes, of the aerials of the radar being simulated. These plan position displays enable interception techniques to be practised by a controller who telephones instructions to the operator of the desk console simulating the fighter, who varies the course of the fighters so as to bring about interception of the bombers. Bomber control may be carried out if required by a controller at another plan position indicator.

An interesting adjunct to the equipment is the simulation of electronic radar counter-measures both by parachuted noise jammers and by the dropping of strips of metal foil ('window'). In both cases means are provided in the equipment to take into account the effect of the prevailing wind on the drift of the jammers.

In the design of this versatile installation, the likelihood of future changes in the performance of aircraft and radar, and of air defence procedure in general, have been borne in mind, and the necessary modifications and additions to the installation to deal with such changes are readily made.

Equipment similar in principle to that demonstrated may be used for simulating marine exercises in which both radar and asdic are used, and it may also be used for training in civil air-traffic controls.

A. F. Wilkins

CHEMISTRY AND QUANTUM CHEMISTRY

IN the course of the past twenty-five years the language of quantum mechanics has invaded almost every branch of chemistry. Often this has been at a very qualitative level involving only such basic concepts as those of stationary states and energy-levels. Many of the most useful ideas, however, are ones which do not belong to accurate quantum mechanics but arose first in certain approximate calculations and have since been developed by using them to explain experimental facts. These range from the idea of a crystal potential which is used to make qualitative predictions about molecular complexes, to ideas such as hybridization and resonance which are used qualitatively to describe the structure and reactivities of molecules. Unfortunately, it is becoming very clear that most of these ideas need careful re-examination both to establish their quantum mechanical status and to show how they can be refined or modified to explain the more extensive and more accurate experimental results now available.

It was very appropriate, therefore, that this problem of the correspondence between the concepts of chemistry and those of quantum chemistry should have been the subject of a panel meeting held at Vålådalen, in the Swedish mountains, during August 26–30 and organized by Dr. P. O. Löwdin, director of the Quantum Chemistry Group in Uppsala. The audience consisted primarily of experimentalists who had spent the previous month there at the summer school on quantum chemistry, and the panel included both chemists and quantum chemists. The meetings were pleasantly informal, and, since the number of prepared contributions was deliberately kept small, there was ample time to discuss fundamental problems.

The theory of molecular structure based on the overlapping of hybrid atomic orbitals which are concentrated in the bond directions was one topic discussed, and in particular the idea of assigning a constant atomic radius to each kind of hybrid. Experimental methods of determining molecular structure using micro-waves, electron diffraction and X-rays were reviewed by Prof. B. Bak (Copenhagen), Prof. K. Hedberg (Oregon), Prof. O. Bastiansen (Trondheim) and Dr. I. Lindqvist (Uppsala), and they reported that the accuracy and flexibility of these methods had recently increased considerably. The results were shown by Prof. Bak and Dr. I. Hjalmars (Stockholm) to imply that the approximation of a constant radius for each hybrid is often accurate to 0·001 A. Furthermore, as Prof. L. Pauling (Pasadena) showed, the rotational barriers can be predicted by including in the hybrids small amounts of higher angular terms, and the experimental confirmation of these predictions was discussed by Prof. L. Pierce (Notre Dame). On the other hand, Dr. Löwdin pointed out that the principle of maximum overlapping is quantitatively inaccurate even on an approximate theory and that the accurate theory does not even give any unique hybrids. In consequence, it is difficult to believe that the hybrids have any physical reality. Prof. R. S. Mulliken (Chicago) agreed that there is still no basic theoretical reason why covalent radii should be so constant.

There was general agreement on the artificial nature of the distinction often made between ionic and covalent binding. Both Dr. S. Lundqvist (Uppsala) and Prof. H. Shull (Indiana) pointed out that ionic wave-functions can sometimes give covalent properties and be almost identical with corresponding covalent wave-functions. This led naturally to a discussion of the method of 'atoms in molecules' which uses such wave-functions. Dr. R. Pauncz (Haifa) showed that, when the method is applied literally to hydrogen, the results are rather poor, but Dr. H. Preuss (Göttingen) defended the method in a modified form. It seems clear that the unmodified free atoms or ions do not provide the best units for describing the compound.

The concept of hyperconjugation is also in some difficulties. This type of delocalization of the electrons plays an important part in the excited states and ionized states of many molecules and in transition complexes, but it is not so clear that it is important in molecular ground-states. The concept was strongly defended by Prof. Mulliken, and he claimed that there is sufficient experimental evidence to substantiate it even for the ground-state. The concept of conjugation also has recently been attacked, but Prof. Mulliken thought this was because the simple Hückel theory sometimes exaggerated its effects, for example, in butadiene, whereas more recent theories give much better agreement with experiment. Dr. R. McWeeny (Keele) argued that the study of diamagnetic susceptibility and proton magnetic resonance gives very strong evidence for conjugation, although Prof. Bak and Mr. R. A. Hoffman (Uppsala) pointed out that some proton magnetic resonance effects in conjugated molecules are not yet understood. Dr. S. Sunner (Lund) talked about difficulties in understanding resonance and strain energies and suggested that these are often due to the use of unrelated or inappropriate reference states.

A point which emerged clearly from the discussion is the growing tension between the so-called semi-empirical methods and those based on *a priori* calculations. Mr. C. Schäffer (Copenhagen), for example, described the successful use of crystal-field theory in explaining the spectra and properties of molecular complexes. Yet, as Dr. Löwdin insisted, the model does break down when refined too far and the empirical values of the parameters do not agree with those calculated. The resonance theory is another example of a theory which is still useful qualitatively and semi-quantitatively despite the fact that some of its assumptions are in serious error. The success of the simple Hückel theory, according to Dr. G. G. Hall (London), is not due to the accuracy of its assumptions but to the mathematical resemblance between its equations and those of a more accurate theory, and it may be that such resemblances occur for other theories.

The urgent need for more accurate theories and concepts appropriate to them was felt several times during the meeting. Dr. H. G. Bennewitz and Dr. G. Gräff (Bonn) underlined it by describing molecular-beam experiments which yield very accurate values of many molecular constants. Prof. F. A. Matsen (Texas) and Dr. Hall favoured the method of different orbitals for different spins as a method more accurate than that of molecular orbitals yet as easy to visualize. There was also a vigorous discussion on the rival merits of natural orbitals and population analysis as methods of understanding complicated wave-functions.

A discussion of the future of quantum chemistry provoked some differences of opinion. In the view of Prof. Mulliken, the calculation of good molecular orbital wave-functions, which is now beginning, will help greatly to clarify molecular structure and will enable generalizations about correlation energies to be made. Dr. Löwdin thought that the effects of correlation and relativistic corrections will be of importance in many chemical problems and should be investigated using more accurate wave-functions. On the other hand, Dr. Hall believed that *a priori* calculations will never be possible for more than a small number of molecules and that it is just as important to study accurately the relations between the molecules of a molecular series. Prof. Matsen considered that the experimentalists' need for concepts with which to organize and understand their results is so urgent that they may be forced to invent these without waiting for the development of quantum mechanical ones. It was Prof. Pauling's hope that the present introspective phase of quantum chemistry, though obviously necessary, will not last very long, since there are many urgent chemical problems which could be solved more easily theoretically than experimentally.

G. G. HALL

NATURAL SELECTION IN MAN

IN a year marked by the celebration of the Darwinian–Wallace centenary, it is fitting that a symposium, sponsored by the Society for the Study of Human Biology and held on November 8 in the Department of Anatomy, University College, London, should have focused attention on modern analyses of the action of natural selection in human populations. The symposium comprised six papers, and in five of these attention was directed to a greater or lesser extent towards genetical matters, knowledge of which is basic to studies of the promotion of evolutionary change by selective forces. In the final contribution, the field was still further expanded by the consideration of a number of broader questions connected with primate (including human) evolution.

The balance of the whole symposium was such as to indicate clearly the extent to which, despite much intensive work, knowledge of many aspects of human inheritance and selection theory still falls short of that now available for some other animal species. Little is known, for example, of the multifactorial control of quantitative human features ; but, on the other hand, a considerable body of information has accumulated in relation to certain groups of major human genes, and several speakers addressed themselves to problems associated with the action of selection upon individuals distinguished by the possession of easily identifiable allelomorphs.

Two of several problems basic to present-day studies of natural selection in man are, as pointed out by Prof. L. S. Penrose (University College, London) in an opening paper, the recognition of these major genetic factors and the determination of the frequencies at which they exist in different populations. The first of these aims has, in many cases, now been attained by analyses of the human pedigrees to the compilation of which much early work was directed. The second has only been achieved on any considerable scale in the case of such factors as those which determine the blood groups, but in this particular case, data are now available from widely scattered regions of the world.

Genetic factors of this type must, as pointed out in the opening paper, have arisen at some time by mutation, but such origins of new variability are rarely recorded. Thus, despite the thoroughness with which the blood-group systems have been studied, mutation in them has not been observed. Indirect evidence, however, indicates its occurrence, sometimes at relatively high rates. Achondroplasia, for example, results from the effect of a single dominant major gene which has in certain populations remained in circulation for long periods. The condition is associated with a marked degree of infertility, and the genetic wastage which thereby results must presumably be made good continually by new mutation.

Recessive genes which, when substituted in double dose into certain genetic complexes, may exert markedly deleterious effects on viability exist in heterozygous form in all populations. They provide a source of potential variability which if liberated would, even in the absence of mutation, form an adequate basis for considerable amounts of evolutionary change. The scope and selective significance of this potential variability are difficult to assess from the available human data, but a reminder of their extent was given by Prof. Th. Dobzhansky, who, as the guest speaker, presented in outline the results of his own extensive work on the hidden genetic variability in wild populations of *Drosophila*.

The selective significance of each factor may be suggested by studies of the effects which it exerts on the processes of growth and development. This aspect of human genetics is still little explored, but a measure of the selective significance of any factor is given by the reproductive 'fitness' which it confers upon the individual. The estimation of fitness presents a number of technical difficulties, which were outlined in a paper by Dr. C. A. Clarke (University of Liverpool). Basically, the problem involves an assessment of the numbers of offspring which reach reproductive age, produced by individuals carrying the mutant allelomorph, relative to those produced by remaining members of the population. The value so obtained measures fitness in only a single selective environment, and, apart from the difficulties associated with the identification of individuals carrying recessive mutants as heterozygotes, sampling bias may be introduced as a result of undue attention being directed towards the families which carry mutant allelomorphs. A further source of inaccuracy arises from the fact that fertility is influenced by numbers of genetic factors additional to the one in question, and these may not be randomly distributed among unrelated individuals carrying the normal and mutant genes. Errors of this type can, to a large extent, be eradicated by the use of sib comparisons, but in this case further uncertainty exists as to whether or not the reproductive capacity of the 'normal' brothers and sisters is representative of that of the population as a whole.

Variations in the fitness conferred by different allelomorphs result in their existing at different frequencies, and it was to a formal mathematical analysis of the maintenance by selective forces of this type of polymorphism that Dr. A. R. G. Owen (University of Cambridge) addressed himself in a paper entitled "Mathematical Models for Selection". In this field, present studies relate exclusively to genes at a single locus, and for stability to be achieved in the relative frequencies of two or more allelomorphs it is necessary that each homozygote should have a fitness less than the average for the population as a whole. The frequency of each allelomorph is broadly related to the fitness which it confers, but when three or more are involved, complex relationships, not only between the viabilities of the various homozygotes but also between those of different heterozygotes, must be satisfied before a stable equilibrium can be achieved. Slight shifts in selective pressure can cause marked changes in the polymorphic balance, while selection acting differentially upon genotypes derived from the male or female parent may result in a dynamic polymorphism in which the frequencies of different allelomorphs vary continually without, however, any allele becoming extinct.

That the maintenance of polymorphism in the frequencies of human genes depends on selective factors now admits of little doubt, and it was in the contribution by Dr. P. M. Sheppard (University of Liverpool) that emphasis was laid on the fact that genes, the presence of which can easily be detected by analyses of characters apparently devoid of selective significance, often exert secondary effects which influence the fitness of the individual to an extent sufficient to establish a polymorphism. Among such genes, the factors which determine the blood groups are probably the best known. Possession of the gene for blood group A is associated with a tendency to develop cancer of the stomach, while the factor for blood group O is, in the presence of the 'non-secretor' gene, associated with an increased incidence of duodenal ulcer. Again, while individuals who are able to taste phenylthiocarbamide are predisposed to the development of diffuse goitre, those unable to taste this compound exhibit an increased incidence of nodular goitre.

In certain instances complex relationships between the selective significance of different series of allelomorphs arise as a result of interactions between the physiological characters which they influence. For example, the selective disadvantage which results from incompatibility between mother and fœtus in either the Rh or ABO series of allelomorphs is largely neutralized if the incompatibility exists in both series simultaneously.

Certain quantitative features (for example, skin colour) are known to have adaptive significance, while others (for example, intelligence) are correlated with fertility and viability. There would seem to be no reason to doubt that the selective forces thus set up have, by their action upon isolated populations, produced the well-defined differences which now exist between the major human sub-groups. In human populations, however, there are, as recently elaborated by Sir Julian Huxley, certain unusual selective forces in operation. These arise from man's unique capacity for abstract thought—a feature which is correlated with the marked cerebral enlargement that has occurred in the course of human evolution. Cerebral enlargement has, in turn, been associated with marked modifications in the cranial and facial skeleton, while concurrently there have arisen in the post-cranial skeleton numerous distinctive features consequent upon man's assumption of an upright posture.

The final paper in the symposium contained a general discussion of certain problems associated with the study of the evolution of these unique human features. Following a brief review of the various phases of the primate radiation between the Eocene and the present day, Dr. E. H. Ashton (University of Birmingham) submitted that as the numbers of available fossil primates are small, and as conspicuous gaps exist in the record of each sub-group of the order, little can be inferred about the anatomical nature of the immediate ancestors of *Homo sapiens*. As a corollary it was suggested that whatever significance may be attached to such controversial groups as *Oreopithecus* and the South African Australopithecinae, it is not feasible to assess the point at which the human stock, which does not appear in an undisputed form until part of the way through the Pleistocene, diverged from the apes, the first representatives of which date from the Lower Oligocene. Consequently, the rate of evolutionary change in each line is indeterminate.

One set of observations does, however, show that in the extant subhuman primates measurable amounts of morphological change can occur in exceptionally short periods of time. A colony of the West African green monkey (*Cercopithecus aethiops sabaeus*) which has been isolated for a mere hundred generations on the West Indian island of St. Kitts now differs significantly in cranial and dental features from the present-day African descendants of the parental stock. The St. Kitts monkey is now not only bigger, but also its cranial and dental dimensions are less variable than in the African variety. On the other hand, while its skull is less symmetrical, certain non-quantitative features of the teeth of the island monkey are now more variable than in the mainland variety. Although the possibility cannot be excluded that this complex of change has resulted from the direct action of a changed environment on an unaltered genetic constitution, parallels with complexes of change recorded in laboratory experiments with lower animals suggest that the differences may have, as a basis, changes in systems of multiple genes. In this case, the observations would represent an example, at present unique, of the effect of selective forces upon a primate population.

E. H. Ashton

WOMEN IN ENGINEERING

PROBABLY the most persuasive case for the employment of professional women in industry has been made by the Women's Engineering Society. Unlike other women advocates who rely either on wistful laments or on emotional over-statements of unestablished truths, the Women's Engineering Society bases its case on hard-won knowledge of industry and on the records of those courageous and enterprising women engineers who have already made successful careers for themselves in industry. In a booklet prepared by members of the Careers Panel of the Society, it is shown that there is now no reason why a girl with talent and determination should not embark on an engineering career with every prospect of success (Training and Opportunities for Women in Engineering, 25 Fouberts Place, London, W.1. 3*s.* 6*d.*). She is advised, however, to equip herself fully with formal qualifications, like membership of professional institutions and those obtained by examination, such as a university degree in engineering or a Higher National Certificate. "Engineering training has two distinct components, theory and practice, and both are equally necessary to the would-be engineer. The former can be obtained in Universities and Technical Colleges, while, for most branches of the profession, the best practical training is provided in industry." It is in obtaining this practical training that the girl student may find herself at a disadvantage compared with her brother. Entry into certain branches of engineering is easier than into others, and there is more prejudice against the employment of women in certain positions than in others. The new branches of engineering such as aeronautics, electrical and electronic engineering, or heating and ventilating, offer an easier entry to women than do the older branches such as marine or locomotive engineering, naval architecture or civil engineering.

There is still a prejudice against putting women in control of large numbers of men, and few firms the employees of which are mostly male would consider appointing a woman as works manager or foreman. There is far less prejudice against the employment of women in scientific work, design or research.

The booklet describes the training and qualifications required in many branches of engineering as well as the posts available when training is complete.

WATER POLLUTION RESEARCH, 1957*

MUCH of this tightly packed report will be of interest only to those who are directly concerned with sewage treatment and pollution, and the thirty-two papers published by members of the staff during the year have nearly all appeared in technical journals. Some of the work is of wider appeal, and merits fuller mention than the rest in a journal of general science such as *Nature*.

Various calculations have been made to find the most economical way of improving the Thames estuary. Aeration of some of the worst inflows has been suggested, but it is shown that the effect of this would not be great. An increase in temperature would lead to an immediately greater oxygen deficit but a corresponding amelioration farther down the river. It has been found that, especially at higher temperature, nitrate may be reduced before the concentration of oxygen approaches zero, a hitherto unsuspected complication in calculations of this kind. Even after the completion by the London County Council in about 1962 of alterations and extensions to its sewage works, the Thames will still be foul. Sulphide, perhaps, will no longer be formed in the central reaches of the estuary, but oxygen concentration will be low.

Fig. 13 of the report shows how oxygenation of water passing over a weir increases with the height of the weir, rapidly at first but gradually more slowly, a 9-foot weir, the highest tested, being only slightly more advantageous than one 8 feet high. The effect depends also on the depth of the basin into which the water falls; with a 5-foot fall the concentration of oxygen increases quite markedly up to a depth of 8 inches, but thereafter is the same for all depths. Another experimental set-up of general interest is the channel for studying temperature gradients. It is 500 feet long and is made by setting baffles across a tank. The object is to study the behaviour of fish in a temperature gradient; but first it will be necessary to study the nature of the gradient under different conditions of flow, humidity and initial temperature. Some figures are presented here, but it is hoped that more will be forthcoming and their relation to the results of theoretical calculations discussed. The continuous recorder for dissolved oxygen, on its way to becoming a standard instrument, has been developed and improved by the incorporation of a device for automatic temperature compensation, which is described.

The amount of effluent necessary for a satisfactory test of toxicity is inconveniently large if the fish used is more than about 1 inch long, and foreign fish have been used since no British species is as small as this when adult. The apparatus designed for routine tests is described and figured. Zinc is shown to be toxic at lower concentration in soft than in hard water, rainbow trout, for example, dying in less than three days in 0·5 p.p.m. zinc in soft water and surviving ten days in six times that amount in hard water. Experiments with a radioactive tracer suggest that the effect of the zinc may be internal and not merely on the gills as hitherto believed.

Various mixtures likely to be produced by coke ovens are more toxic than pure phenols, and their effects are enhanced by low oxygen concentration. Biological treatment is sometimes successful, but not when substances containing much ammonia are present. Cyanide, too, has been successfully broken down in a biological filter, and experiments have been carried out on an anaerobic digestion process for certain trade wastes. It has been found a satisfactory method of dealing with the effluents from slaughter-houses and whisky distilleries.

The nature and concentration of the constituents of domestic sewage, about which little is known, are under investigation. It now seems clear that synthetic detergents reduce the rate at which oxygen is absorbed in the activated sludge process, and this may account for reports of decreased efficiency of certain plants in recent years. T. T. MACAN

CHEMICAL DESTRUCTION OF MATURE PERITHECIA OF *MYCOSPHAERELLA PINODES*

By M. V. CARTER
Waite Agricultural Research Institute, Adelaide

RECENT research work with dinitro-ortho-cresol, pentachlorophenol (and their sodium salts) and phenyl mercury compounds as eradicant fungicides has been aimed mainly at preventing the normal maturation of ascocarps of various fungal pathogens, as distinct from destroying mature ascocarps. Pathogens in which ascospore discharge has been controlled successfully by the application of these compounds prior to maturation of the perithecia apparently all belong to the group of Ascomycetes which complete their life-cycles during a long over-winter saprophytic phase in fallen leaves, mummified fruits, or branch cankers, for example, *Venturia inequalis*[1], *Pseudopeziza ribis*[2], *Sclerotinia* spp.[3], *Nectria galligena*[4].

In South Australia, where large areas of garden peas for fresh marketing are grown under sprinkler irrigation in districts of low natural rainfall (12 in. or less per annum), extensive damage to crops by *Mycosphaerella pinodes* is common. Under optimum conditions, mature perithecia of this fungus may be produced within two weeks from the time of infection: there are thus many generations of ascospores during a single pea-growing season.

Phenyl mercuric chloride was found to be ineffective in destroying mature perithecia of *M. pinodes* when applied at a concentration of 0·1 per cent, as used for autumn spraying for eradication of *V. inequalis*.

In the first series of laboratory tests with pentachlorophenol, an oil-and-water emulsion containing 0·75 per cent of the chemical was applied by means of a 'Rega' hand atomizer to a series of 5–10 gm. samples of heavily infected pea straw from the 1957 crop, collected from the field in February 1958. Control samples were treated with distilled water. Beginning two days after the treatments were applied, and at weekly intervals thereafter for the next seven weeks, ascospore discharge was tested by immersing each sample in water for 5 min., draining for 5 min., and suspending in a wire basket under a bell-jar 6–7 in. above the orifice of a Hirst-type spore impactor[5], which was then operated for 1 min.

Table 1. NUMBERS OF ASCOSPORES* OF *Mycosphaerella pinodes* DISCHARGED FROM PEA STUBBLE SAMPLES AFTER TREATMENT WITH 0·75 PER CENT PENTACHLOROPHENOL

Days after treatment	Control (water only) 1	2	3	4	5	0·75 per cent pentachlorophenol 1	2	3	4	5

* Each count is the sum of 10 traverses across the zone of spore deposit on a microscope slide, using a magnification of 480

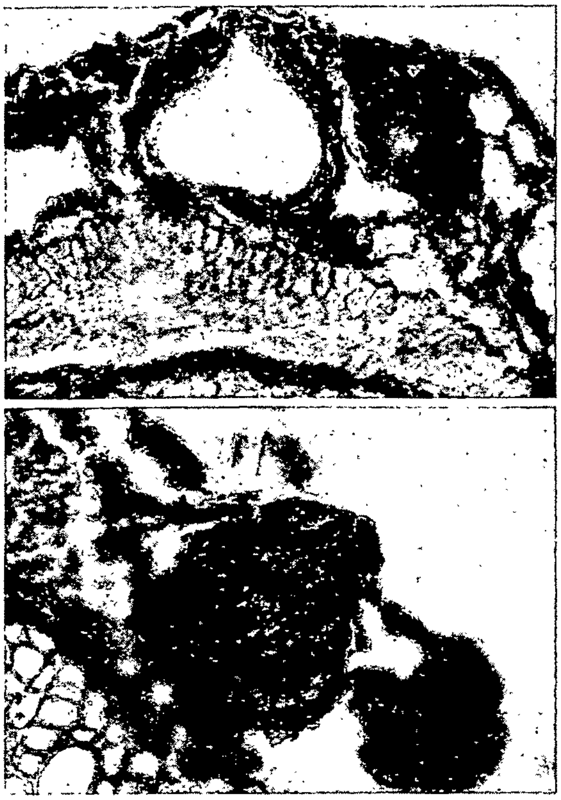

Fig. 1. Top, perithecia of *M. pinodes* treated with 0·75 per cent pentachlorophenol; bottom, normal (untreated) perithecium of *M. pinodes*

The spore counts given in Table 1 suggested that this concentration of pentachlorophenol had a powerful fungicidal effect on mature perithecia of *M. pinodes*, but that the method of application had not given complete coverage.

The second series of laboratory tests was designed to determine the effect of a range of concentrations of pentachlorophenol on 10-gm. samples which were momentarily immersed in the emulsion in order to ensure complete coverage. Spore discharge was assessed in the same way, beginning on the second day after treatment and continuing thereafter at weekly intervals for five weeks. Spore counts are given in Table 2, and these indicate a highly efficient kill of perithecia with all concentrations of pentachlorophenol down to 0·2 per cent.

After each of the first four discharge tests, the samples were allowed to dry in air. After the fifth discharge, all the samples were showered with ascospores of *M. pinodes* and incubated moist in closed containers at room temperature to determine whether recolonization by the fungus could occur at this stage. Straws untreated with pentachlorophenol but steam-sterilized were also subjected to a similar inoculation and incubation.

A very heavy mycelial growth was present on the steam-sterilized straws after incubation for five days; that on the unsterilized untreated controls was less conspicuous, possibly due to partial inhibition by strong bacterial growth. A few isolated colonies were noted on all the samples treated with pentachlorophenol except those which had received the 2 per cent treatment.

In order to examine histologically the effect of pentachlorophenol on the perithecia, representative straws from 0·75 per cent pentachlorophenol and from control samples were embedded in paraffin wax and sectioned by microtome at 10μ. The chemical completely destroyed the contents of the perithecia, which appeared either empty or with a few disorganized remains in the asci, as shown in Fig. 1 (top). Sections of normal untreated perithecia are shown in Fig. 1 (bottom).

Preliminary tests have shown that dinitro-ortho-cresol (0·2 per cent) and dinitro-secondary butylphenol (0·2 per cent) may be expected to give similar results.

Field experiments with certain of these chemicals are proceeding; but observations to date indicate that the technical difficulties of obtaining a sufficiently complete spray coverage of the pea stubble will present a serious obstacle to successful application of the method for field control of the pathogen.

OXIDATION OF ASCORBIC ACID AND SIMILAR REDUCTONES BY NITROUS ACID

By DR. C. A. BUNTON

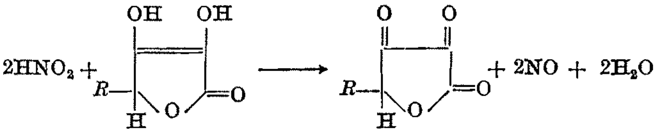
Department of Chemistry, University College,
London, W.C.1

AND

PROF. H. DAHN and DR. LOTTE LOEWE

Organisch-chemische Anstalt der Universität,
Basel

THE reaction between ascorbic acid and sodium nitrite or nitrous acid was first observed by Karrer and Bendas[1]. This reaction is general for reductones (that is to say, enediols stabilized by conjugation to a carbonyl or similar group)[2,3]; it has the characteristics of a typical oxidation-reduction process, and gives quantitative formation of nitric oxide and dehydro reductone. For example:

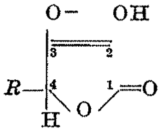


(I*a*), Ascorbic acid (R = $CH_2OH.CHOH—$)
(I*b*), Phenyl hydroxytetronic acid[3]
(R = $C_6H_5—$)

(II*a*), (R = $CH_2OH—CHOH—$)
(II*b*), (R = $C_6H_5—$)

The optimum conditions for these reactions (in aqueous solutions at $pH < 5$) are similar to those in which nitrosation at nitrogen and oxygen occurs[4,5], and we sought and have found a parallel between the oxidation of reductones, and the diazotization of aromatic amines[4], and the exchange of oxygen atoms between water and nitrous acid[5].

The compounds (I*a*) and (I*b*) have characteristic absorptions[6] which are more intense than those of the dehydro reductones (II*a*) and (II*b*) and of nitrous acid, and the reaction can be followed by spectrophotometric methods. The 3-hydroxyl group of (I*a*) and (I*b*) is acidic ($pK_a \sim 4$), while that on C–2 is enolic ($pK_a \sim 12$)[7]. Thus at $pH < 5$ the acid (I) and its mono-anion (III) co-exist.



(III)

The kinetics of the oxidation of ascorbic acid (and to a limited extent of phenyl hydroxytetronic acid (I*b*)) have been examined in detail at 0° C. in aqueous dioxan. A few runs were made in water, but in some conditions the reaction in water is too fast for convenient measurement. In all cases the concentration of the reductone ($0 \cdot 1$–$0 \cdot 2 \times 10^{-3}$ *M*) was much less than that of the nitrous acid ($0 \cdot 8$–$8 \cdot 0 \times 10^{-3}$ *M*).

With sodium nitrite in excess over nitrous acid (pH 3–4 in water) we observe the rate-law for reactions in both water and aqueous dioxan:

$$v = k_2 [HNO_2]^2$$

The kinetic form of an individual run is of zeroth-order in reductone and the rate is almost independent of the nature and concentration of the reductone:

$$\begin{aligned} (\mathrm{I}a),\ 10^2 k_2 &= 1 \cdot 7 \ (\mathrm{mol.}^{-1}\ \mathrm{l.sec.}^{-1}) \\ (\mathrm{I}b),\ 10^2 k_2 &= 1 \cdot 5 \ (\mathrm{mol.}^{-1}\ \mathrm{l.sec.}^{-1}) \\ (0^\circ\ \mathrm{C.};\ \mathrm{dioxan} &: \mathrm{water} :: 40 : 60\ \mathrm{v/v}) \end{aligned}$$

Following the interpretation given to such a kinetic form in the diazotization of the aniline[4], we conclude that the step *determining the rate* of the reaction is the formation of dinitrogen trioxide.

Reaction path A :

$$\begin{gathered} 2HNO_2 \rightleftharpoons H_2NO_2^+ + NO_2^- \\ (1) \\ \downarrow \\ H_2NO_2^+ + NO_2^- \rightleftharpoons N_2O_3 + H_2O \\ (2) \\ N_2O_3 + \text{reductone} \rightarrow \text{intermediate (IV)} \\ (3) \\ (\mathrm{IV}) \xrightarrow[\text{(fast)}]{\text{nitrous acid}} (\mathrm{II}) \\ (4) \end{gathered}$$

In this acidity region most of the reductone is present as a mono-anion (III); we assume that the dinitrogen trioxide reacts rapidly with this mono-anion (step 3), to give an intermediate (IV), which then reacts rapidly with a further nitrous acid species to give the final products. (The probable nature of the intermediate is discussed below.) This kinetic scheme requires that the rate of reaction of the reductone in water should be close to that of the zeroth-order diazotization of aniline[4], and the oxygen exchange of nitrous acid via dinitrogen trioxide[5]: this is so within the limits of experimental uncertainty.

$$\begin{aligned} k_2 &= 0 \cdot 49 \ (\mathrm{mol.}^{-1}\ \mathrm{l.sec.}^{-1}) \ (\text{oxidation of } (\mathrm{I}a)) \\ &= 0 \cdot 85 \ (\mathrm{mol.}^{-1}\ \mathrm{l.sec.}^{-1}) \ (\text{diazotization})^4 \\ &= 0 \cdot 53 \ (\mathrm{mol.}^{-1}\ \mathrm{l.sec.}^{-1}) \ (\text{oxygen exchange})^5 \\ &\quad (0^\circ\ \mathrm{C.};\ \text{water}) \end{aligned}$$

At the other extreme of our acidity-range (with $[HClO_4] \gg [HNO_2]$) we observe a different kinetic form:

$$\begin{gathered} v = k_3{}^{0H} [H^+] [HNO_2] [\text{ascorbic acid}]; \\ k_3{}^{0H} = 7 \cdot 5 \ (\mathrm{mol.}^{-2}\ \mathrm{l.}^2\ \mathrm{sec.}^{-1}) \\ (0^\circ\ \mathrm{C.};\ \text{dioxan} : \text{water} :: 40 : 60\ \mathrm{v/v}) \end{gathered}$$

(So far, this region has been explored only for the oxidation of ascorbic acid in aqueous dioxan.) With an excess of perchloric acid (about $0 \cdot 1$–$1 \cdot 0$ *M*) the concentration of ascorbate ion is very low, and we consider the mechanism to be a slow reaction between the nitrous acidium ion (V) and ascorbic acid.

Reaction path B :

$$\begin{gathered} H^+ + HNO_2 \rightarrow H_2NO_2^+ \ (\mathrm{V}) \\ (\mathrm{V}) + \text{ascorbic acid} \rightarrow \text{intermediate (IV)} + H^+ \end{gathered}$$

followed by a rapid reaction of the intermediate (IV). This process has its analogy with N- and O-nitrosations, for example, the diazotization of aromatic amines in acid[4], and the acid catalysed hydrolysis of alkyl nitrites[8].

In the acidity-range between those which show mechanisms *A* and *B* there is a region in which the kinetics are of mixed order. Part of the reaction proceeds by mechanism *B*, but there is also a rate term which is second order in nitrous acid and first order in stoichiometric reductone. A similar kinetic form has been observed for reactions between nitrous acid and both aliphatic and aromatic amines[4,9]. It arises because in this region dinitrogen trioxide is in facile equilibrium with nitrous acid (steps 1 and 2 of mechanism *A*), but the proportion of the highly reactive reductonate ion is now very low (< 0·1 per cent), and so the reaction with dinitrogen trioxide (step 3 of path *A*) is slow. A detailed examination of the effect of changes in acidity and nitrous acid concentration upon the reaction-rate between nitrous and ascorbic acids shows that in the region $[H^+] = 10^{-4}$–10^{-3} *M*, dinitrogen trioxide reacts with both ascorbic acid and ascorbate ion, and it is possible to estimate the relative reactivities towards dinitrogen trioxide:

$$v = [HNO_2]^2 \{k_3{}^0 [\text{ascorbic acid}] + k_3{}^- [\text{ascorbate}]\}$$

$k_3{}^0 = 73$ ($\mathrm{mol.}^{-2}\ \mathrm{l.}^2\ \mathrm{sec.}^{-1}$); $k_3{}^- = 1 \cdot 15 \times 10^5$ ($\mathrm{mol.}^{-2}\ \mathrm{l.}^2\ \mathrm{sec.}^{-1}$) (0° C., dioxan : water 40 : 60 v/v).

Thus we have reactions of the powerfully electrophilic nitrous acidium ion with the undissociated reductone, and of the weakly electrophilic dinitrogen trioxide with both the undissociated reductone and its more reactive anion.

Chloride and bromide ions catalyse the oxidation of ascorbic acid by nitrous acid by forming nitrosyl halides, which are themselves powerful nitrosating agents[4].

$$H_2NO_2{+} + X^- \rightleftharpoons NOX + H_2O$$

$$NOX + \begin{Bmatrix}\text{ascorbic acid}\\ \text{ascorbate ion}\end{Bmatrix} \rightarrow \text{intermediate (IV)} + \begin{Bmatrix}HX\\ X^-\end{Bmatrix}$$

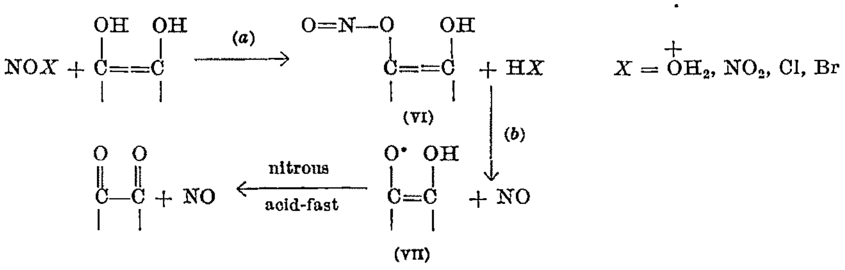
$$(X = Cl, Br)$$

From our kinetic results we can calculate specific rate-constants for the processes, and estimate the relative reactivities of various species towards dinitrogen trioxide and the nitrous acidium ion. In making these calculations we have ignored effects due to activity changes; these should not be large because the ionic strengths of the solutions are low, and approximately constant. Some of the numerical values are uncertain, because they are derived from small differences between large quantities.

We can formulate the reaction between a nitrosating agent and a reductone in various ways. Perhaps the simplest is a preliminary electrophilic attack upon the reductone (*a*), with formation of a nitrite (VI), which then decomposes (*b*).

It is, of course, possible that steps (*a*) and (*b*) may be synchronous, and the process would then be considered as a transfer of a single electron to the nitrosating agent. In either event we conclude that the first step of reaction between a nitrosating agent and a reductone, forming the semiquinone (VII) (which may be identical with the above-mentioned 'intermediate' (IV)), is followed by a rapid reaction between (VII) and nitrous acid, or some species in equilibrium with it.

It seems to us that there is, therefore, a very close similarity between this oxidation – reduction reaction and the well-characterized heterolytic nitrosations by electrophilic reagents.



This work forms part of a research programme on reductones, sponsored by the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung, to which we express our thanks. A full account of the present work will be given in *Helvetica Chimica Acta.*

A TWO-DIMENSIONAL PAPER CHROMATOGRAPHIC METHOD COMBINING ION-EXCHANGE AND PARTITION TECHNIQUES

By C. S. KNIGHT

Research Laboratories, W. and R. Balston, Ltd., Springfield Mill, Maidstone, Kent

ALTHOUGH the two-dimensional paper chromatographic method has been successfully applied to separations involving a wide range of substances, improvements and modifications are continually being proposed to make this technique even more discriminating.

Separations can often be improved by increasing the complexity of one or more of the conditions under which a chromatogram is developed, as, for example, in the use of three- or four-component solvent mixtures. On the other hand, the use of simple conditions to increase the reproducibility is often insufficient to effect an adequate separation. Thus, some approach between the two extremes has to be adopted. The present method, however, offers a means of increasing reproducibility in addition to separability.

This new approach to paper chromatography comes as a result of the development of a range of Whatman ion-exchange celluloses in these Laboratories. These new materials have been prepared by introducing acidic or basic groups into the cellulose molecule such that, under favourable conditions, ion-exchange involving these groups will be the dominating factor in a chromatographic separation[1]. Where, however, it is possible to suppress the activity of these groups such that ion-exchange is no longer the dominating factor, any chromatographic separations under such conditions will be largely as a result of a partition-type mechanism similar to that on unmodified cellulose. On the one material, in paper form, therefore, it is possible to combine ion-exchange and partition techniques in the form of a two-dimensional chromatogram, and this very simply is the basis of the method described below.

The ion-exchange materials investigated contained medium or weak strength functional groups such that where necessary their ion-exchange properties can be suppressed to varying extents by addition of acid or alkali to a developing organic solvent. Details of some separations investigated are as follows.

(1) Phosphorylated cellulose, containing dihydrogen phosphate groups, was used in the form of its mono-ammonium salt. A mixture of copper, manganese, cobalt, cadmium, iron, bismuth, zinc and mercury was applied as a spot near one corner of a

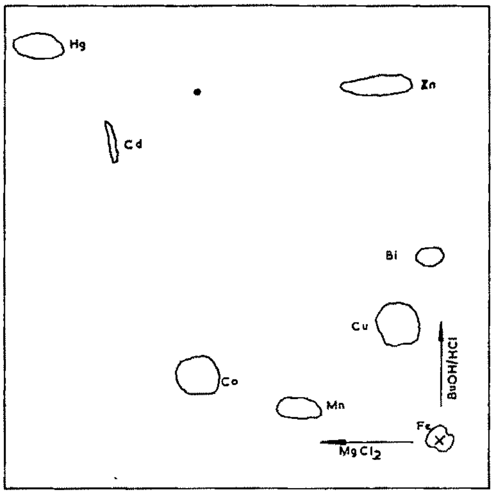

Fig. 1

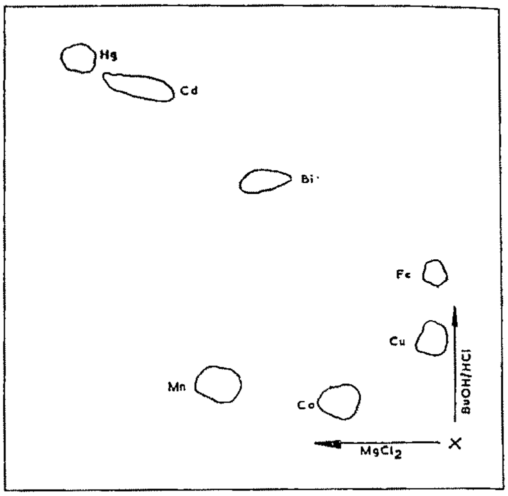

Fig. 2

14-in. square sheet of paper. The organic phase of a mixture of butanol saturated with 2 *N* hydrochloric acid was used as first solvent in a downward direction, after which the sheet was dried over ammonia to neutralize excess acid and convert the paper to its original form. The second development, in a downward direction at right angles to the first development, was with *N* magnesium chloride solution. The choice of this eluting agent stems from its successful application by other workers^2. The separated spots were detected by spraying with a pentacyanoammino-ferrate/rubeanic acid complex, which produces characteristic colours with a large range of cations^3.

Fig. 1 is a map of the spots on the completed chromatogram. The position of the spots in the first direction is similar to the positions expected on unmodified cellulose. Iron occupies an anomalous position possibly due to complex formation between it and the phosphate groups on the paper^4. The flat shape of the cadmium spot in the magnesium chloride direction is probably due to the occurrence of a magnesium – ammonium boundary at this point.

(2) Carboxylated cellulose (type 2) containing primary carboxyl groups was used in its hydrogen form. A mixture of copper, manganese, cobalt, cadmium, bismuth, iron and mercury was applied as a spot near one corner of a 14-in. square sheet of paper. Development was carried out in two directions, using the same solvents and technique as in (1).

Fig. 2 is a map of the spots on the completed chromatogram. In the first direction, iron has assumed a more typical position, but in the magnesium chloride direction the position of bismuth is not that expected of a trivalent ion.

(3) Aminated cellulose containing aminoethyl groups was used in the form of its hydrochloride. A mixture of copper, cadmium, lead, bismuth and mercury was applied as a spot near one corner of a 14-in. square sheet of paper. The first solvent was a butanol–2 *N* hydrochloric acid mixture as before. After drying at room temperature, without addition of ammonia, the chromatogram was developed in the second direction with *N* hydrochloric acid^2. The positions of the spots were revealed by spraying with ammonium sulphide solution.

Fig. 3 is a map of the spots on the completed chromatogram. R_F values in the first direction are lower than in 1 and 2 and it is tempting, from the position of the spots, to assume a mechanism largely of partition type with the lower R_F values being due to the increased polarity of the cellulose. However,

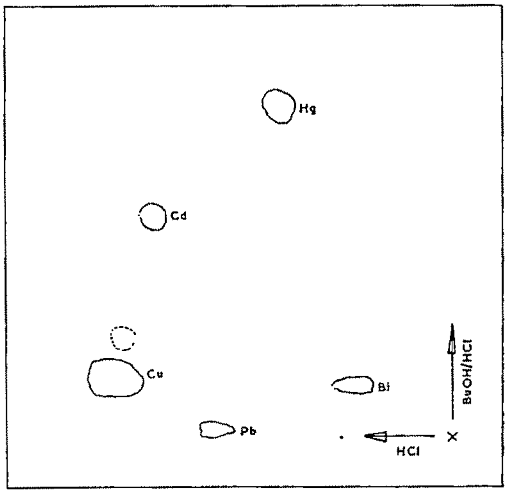

Fig. 3

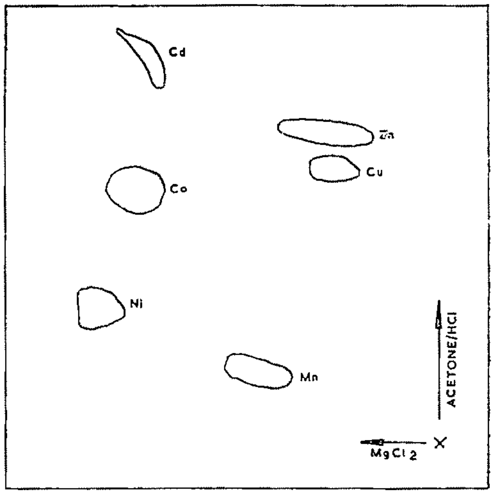

Fig. 4

in this particular case where the ionization of the functional groups is not suppressed it is possible that the mechanism is of a more complicated nature. The metals separate as their anionic complex chlorides in the second direction. The spot represented by the dotted outline was due to a trace of iron in the original mixture.

Slight variation of the relative positions of the various cations on the different materials in the butanol–hydrochloric acid direction is to be expected, the weak carboxyl exchanger giving a separation closest to that obtainable on unmodified cellulose. From Figs. 1, 2, and 3, however, it can be seen that good separations can be obtained on relatively small areas of paper. Fig. 4, for example, illustrates a separation of six metals on an 8-in. square of phosphorylated paper by an ascending technique, using an acetone–hydrochloric acid–water (50 : 5 : 5) mixture in the first direction and *N* magnesium chloride in the second.

The advantages of the increased separation by the above method will be emphasized in the separation of a series of related substances where it is common in conventional two-dimensional paper chromatography to obtain separations in which the majority of the spots are concentrated in one diagonal half of the paper, since in many cases the relative R_F values of the series of substances are similar in a whole range of different organic solvents.

To sum up, therefore, compared with the conventional two-dimensional chromatogram, the method described above, by virtue of the incorporated ion-exchange characteristics, provides an overall increase in separability, speed and reproducibility.

This method is being applied to amino-acid separations with promising results. Details of this, together with a fuller report on the inorganic separations, will be published later.

I wish to thank the Directors of W. and R. Balston, Ltd., for permission to publish this work.

NATURE OF THE VIBRATO AND THE CONTROL LOOP IN SINGING

By Dr. J. A. DEUTSCH and J. K. CLARKSON
Institute of Experimental Psychology, University of Oxford

ANY attempt to analyse the control mechanisms in the human operator is greatly facilitated if we can control all the information which is fed from the output back into the input. But whereas in most skills proprioception, which is resistant to such control, is of importance, in singing the role of the auditory pathway is paramount. This can readily be heard if a subject is asked to sing a simple musical scale when a strong masking noise obliterates his hearing of his own performance. He will sing badly out of tune.

As a result, the investigation into the control mechanisms of skill has shed some light on the cause of fluctuations in frequency in the singing human voice. It has long been known that when a subject attempts to sing a steady note there is a periodic fluctuation in frequency of approximately 5–6 cycles per second. Suspecting that this tremor might represent the oscillations due to a control mechanism utilizing auditory feedback, the senior author began a series of experiments, now concluded by both of us, which show that this supposition is at least partially the case.

We find that if a delay is interposed between the subject's singing a note and afterwards hearing it, the time taken for one cycle of fluctuation increases directly with the interval of incorporated delay, and that the same is true of the amplitude of the deviation from the note he is attempting to sing. These points are illustrated in Figs. 1 and 2, respectively. Records of the frequency fluctuations were obtained through an audio-frequency meter devised by the senior author[1]. Samples of these records with no artificial delay and with 0·366 sec. delay are shown in Fig. 3. The voice was delayed by the procedure of recording on tape at one point and taking off at an adjacent point through another lead. The output was then greatly amplified and fed back to the subject through a pair of earphones. The loudness of the note fed back in this way was sufficient to mask the sound of the subject's own undelayed voice.

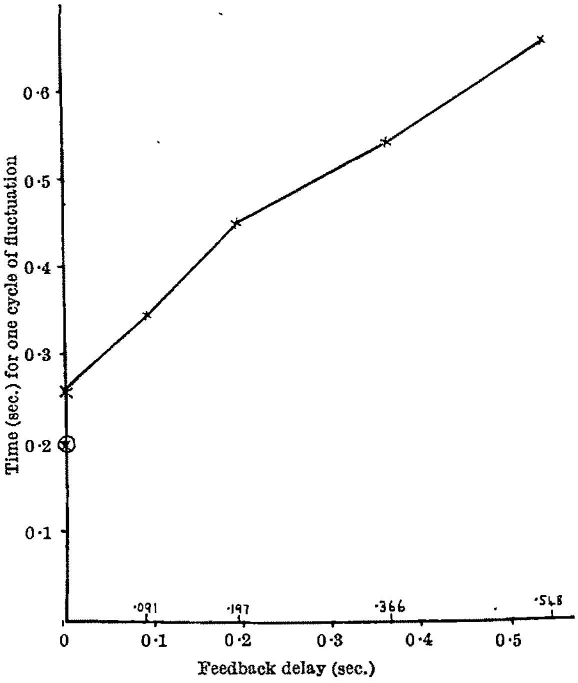

Fig. 1. Average time taken for one cycle of fluctuation under varying feedback delays. Each point represents an average for thirteen subjects. The encircled point on the abscissa gives the average time for the normal voice. The first point of the graph gives the average for monitoring through earphones without an incorporated delay

The importance of the findings is as follows.

The voice is largely controlled by the auditory message generated by it (this probably only applies to the fine frequency control of the voice, for at very long delays the deviations from the desired note do not reach the amplitude predicted on this mechanism alone).

The control does not seem to be applied in proportion to the magnitude of the error as the correction made in response to the error continues smoothly until it has led the subject into an error of opposite sign which is of equal amplitude. Further experiments to check this view have already been undertaken with an artificial larynx where the amount of change perceived by the subject can be instantaneously exaggerated to him. Using this type of apparatus, if we invert the direction of change it should be possible to discover whether the sign as well as the magnitude of error is disregarded by the mechanism determining the corrective movements. We should then be able to speculate more accurately about the mechanisms of skilled performance generally.

It appears that the time taken to react to an error in this kind of skilled performance is rather lower than might have been suspected from the existing data on reaction times and refractoriness. It must be remembered that a subject can only start reacting to his own error when the note produced by the error has exceeded the difference threshold between itself and the note he is aiming to sing. From the records which we have obtained of the subject monitoring his own performance without the intermediacy of headphones (that is, in the natural way) we conclude that the subject's reaction time is 0·10 sec., even if we credit him with an ability to discriminate infinitely small variations in pitch, but of course even this very low figure should be substantially smaller. It is to be noted that the period of oscillation increases when the subject is monitoring himself through earphones, utilizing a note which has been instantaneously amplified. This we take to be due to an increase in the differential threshold in pitch in the monitoring process when the subject is presented with a sound less familiar to him than the sound of his natural voice. (This observation tends further to substantiate our claim that in the frequency vibrato we are dealing with a phenomenon of auditory feedback control.) The mean auditory reaction usually quoted[2] is 0·15 sec. Such a time increases in the ordinary situation if the signals follow close on each other, as has been shown by R. Davis[3], following the work of Craik and Welford on serial reaction times. However, the corrections we note are often obscured by a higher-frequency tremor, and this will make our estimate inaccurate.

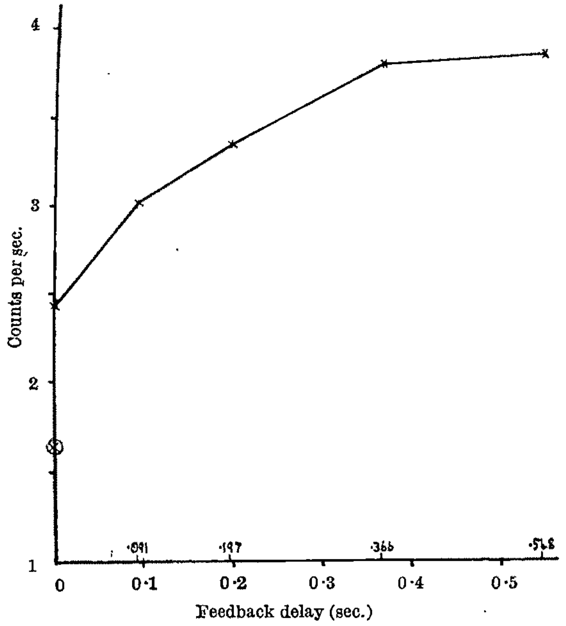

Fig. 2. Average amplitude in cycles of frequency fluctuation under varying conditions of delay. The encircled point on the abscissa gives the average for the normal voice. The first point of the graph gives the average for monitoring through earphones without an incorporated delay. (All points give averages for thirteen subjects)

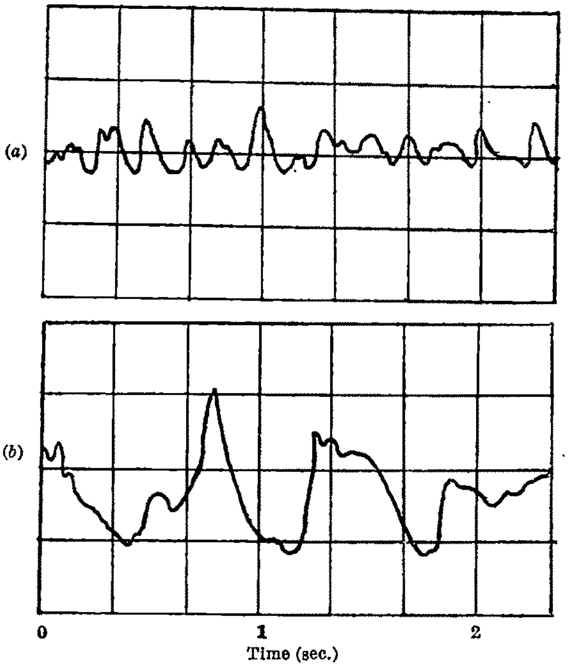

Fig. 3. (a) Frequency fluctuations of normal voice singing a note of 180 c./s.; (b) fluctuations of same voice with feedback delay of 0·366 sec. (It can be seen that in both records there are superimposed higher-frequency tremors of unknown origin)

It also appears that the corrections are made to differences in pitch which would, from the results of the usual experiments, be below the threshold of discrimination. It is hoped that with the method of the artificial larynx outlined above it may be possible to determine more precisely both the size of reaction time to a signal in this situation and the amount of frequency change necessary to trigger off such a control movement. At present we can only say that the corrective movement occurs when the deviation has reached only a matter of 1·6 c./s. when singing a 120 c./s. note under normal conditions. This fixes the largest possible threshold if we assume that the reaction time is vanishingly small. Both the small reaction time and threshold may be due to the high probabilities of the signal and this requires to be investigated further.

We are indebted to the Medical Research Council for grants in aid for apparatus and a grant for scientific assistance.

We should also like to thank Prof. R. C. Oldfield for the encouragement he has given us and for the facilities he has granted us in his laboratory.

It may be noted that for ages as great as those of the meteorites, ~$4 \cdot 5 \times 10^9$ years, there is a more noticeable discrepancy between α- and β-ages. Thus for the case of the meteorites there may be a better chance to confirm or reject the hypothesis of a varying weak interaction constant. Unfortunately, because of the discordance between lead–lead[8] and uranium–lead[9] ages of meteorites, there is reasonable doubt about the accuracy of the ages based on lead ratios. Also, because of the spread in ages obtained from the potassium-40–argon-40 method[10,11], there is reason for believing that some argon has been lost. This throws this determination somewhat in doubt. The strontium-87–rubidium-87 determinations[12] are few and may not have the necessary reliability.

It is concluded that there is no present evidence sufficiently reliable to rule out a variation with time in the β-decay rate.

The De Haas–Van Alphen Effect in Copper

THE de Haas – van Alphen effect in copper has been observed in a whisker made by the Brenner method[1] and oriented with the [111] axis along the field (see Fig. 1); the period is about $1 \cdot 7 \times 10^{-9}$ gauss^{-1}, which is close to the value for a free electron sphere of one electron/atom and not inconsistent with the Fermi surface proposed by Pippard[2]; the effective electron mass as estimated from the temperature variation of the effect is about 1·3 times the free electron mass.

Previous negative results[3,4] may have been due to (*a*) crystal imperfections, (*b*) eddy currents associated with the impulsive field, (*c*) non-occurrence of the effect in certain crystal directions. Copper whiskers are usually very well oriented along one of the principal crystal directions and are of good quality as crystals; thus they are particularly favourable as regards (*a*), since the influence of a given degree of imperfection is least along a direction of symmetry. Moreover, a whisker provides in a natural way a very thin crystal wire and thus helps as regards (*b*); the diameter of the whisker used was about 0·2 mm. It is interesting to note that three other whiskers, two oriented along [100] and one along [110], showed no de Haas – van Alphen effect; this may well be merely because of inadequate sensitivity (in the successful observation the oscillations had only about ten times the noise amplitude), but it is possible that the magneto-resistance effect is particularly high for the [111] direction[5–7] and not for the other directions, thus making the [111] whisker particularly favourable as regards reducing eddy currents.

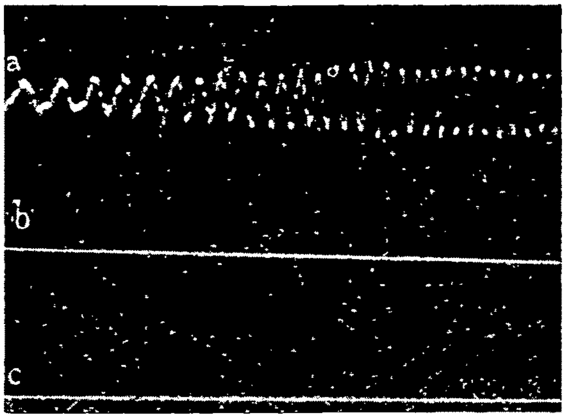

Fig. 1. Trace *a* shows the amplified output from a pick-up coil containing the [111] whisker at 1·1° K. in a magnetic field H of about 72,000 gauss, which drops by about 250 gauss across the picture during a time of sweep of about 0·6 msec. This drop is indicated by the slight decrease of separation between traces *b* and *c*, which is a measure of the variation of $(H - 67{,}000)$ gauss. The shortening of the interval occupied by each successive period is due to the increasing rate of decrease of the magnetic field from left to right

The discovery of a positive effect in copper removes the suspicion that the earlier negative results in monovalent metals may have been due to fundamental rather than technical reasons, and thus opens the way to a detailed investigation of the electronic structure of these metals.

It is a pleasure to acknowledge the hospitality of the General Electric Research Laboratory, Schenectady, N.Y., during last September, which provided the opportunity of obtaining the whiskers, and I should like particularly to thank Mrs. Ethel Fontanella, of General Electric, for her assistance in preparing the whiskers for use, and Mr. Harry Davies for his assistance in the experiments.

Crystal Structure of Foshagite ($Ca_4Si_3O_9(OH)_2$)

WE have recently made some predictions about the crystal structure of foshagite, based on a study of the dehydration process at 700° C. together with electron diffraction and X-ray fibre evidence[1]. There were strong indications that the structure consists of calcium and hydroxyl ions, and metasilicate chains resembling those in wollastonite[2], and the approximate positions of the calcium ions were suggested. A complete trial structure is now postulated, and more detailed consideration of the X-ray evidence shows that it is essentially correct.

The structure is shown in Fig. 1 with that of parawollastonite (monoclinic β-monocalcium silicate) for

Fig. 1. Projections of the structures of foshagite and parawollastonite. Full lines define unit cells. Broken lines in figure for parawollastonite outline pseudo-cell of foshagite, showing how the calcium positions are related in the two structures

comparison. As previously suggested, the positions of many of the calcium ions, and also those of many of the oxygens, are nearly the same in the two structures, but there are fewer metasilicate chains in foshagite, the excess charge being balanced by hydroxyl. In both cases, the calcium ions lie in distinct planes (201 for parawollastonite and 102 for foshagite). Within these planes, they occur in rows parallel to *b*, adjacent rows being separated by either 3·1 or 4·7 A. The 3·1 A. separation is the same as the corresponding one in calcium hydroxide, and each metasilicate chain is kinked so that the oxygens on one side can participate in formation of an octahedral Ca—O sheet resembling that in calcium hydroxide (Fig. 2). In foshagite, some of the oxygen positions are occupied by hydroxyl. On the opposite side of each chain, the oxygens are farther apart in projection, causing the octahedral sheets to be split into bands. These are four calcium ions wide in foshagite and three in β-monocalcium silicate, corresponding to the Ca : Si ratios of 4 : 3 and 3 : 3 respectively.

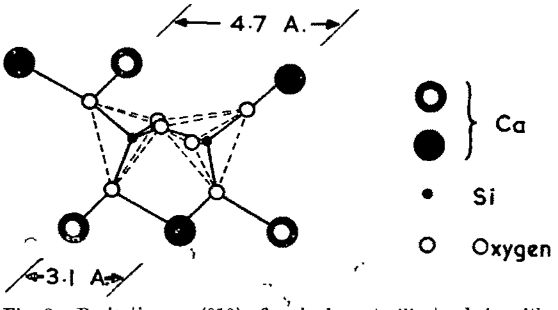

Fig. 2. Projection on (010) of a single metasilicate chain with co-ordinated calcium ions, showing Ca—Ca distances in projection of 3·1 and 4·7 A.

As crystals of foshagite sufficiently large for single-crystal X-ray work are unknown, the structure was tested by comparing calculated structure factors with ones derived from X-ray fibre rotation photographs. The *R*-factor for the first fifty-eight *h0l* reflexions was 0·29, and that for the first thirty-six *h2l* reflexions was also 0·29. In view of the difficulties of measuring the intensities accurately, and also of indexing some of the reflexions, this was considered adequate proof that the structure was basically correct, and refinement will be attempted. No attempt was made to calculate intensities for reflexions with *k* odd, which are extremely weak and streaked because of mistakes of *b*/2 in the positions of the metasilicate chains.

The unit-cell given previously (*a*, 10·32 ; *b*, 7·36 ; *c*, 14·07 A. ; β, 106·4° ; *A*-face centred) is confirmed, but it is only geometrically monoclinic, and the true cell is triclinic with half the volume and space-group $P\bar{1}$. Provisional atomic co-ordinates are given (Table 1) in terms of the *A*-centred cell.

The relation of foshagite to β-monocalcium silicate is somewhat analogous to that of members of the chondrodite series to olivine; the two minerals could be regarded as the first two members of a series with general formula $Ca_{3+n}Si_3O_9(OH)_{2n}$. It is structurally possible that more basic members of this series may exist and hillebrandite ($2CaO.SiO_2.H_2O$) may be the member with $n = 3$; this hypothesis is being investigated. The crystal structure of foshagite was briefly described at the symposium on "Kristallchemie und Strukturanalyse", Berlin, March 1958, and a full account will later be published elsewhere.

Electron Affinity of Atomic Lithium

Recent measurements[1] of some atomic electron affinities based on observations of the optical threshold for electron detachment give rise to a need for theoretical calculations of electron affinities for comparison. However, none of the empirical extrapolation methods has a justifiable theoretical basis for the extension from atoms and positive ions with attractive Coulomb fields to negative ions with fields of short range. In the case of H^- the extrapolated value[2] of the electron affinity is in good agreement with the value obtained by quantum-mechanical calculations[3], but in the case of Li^- the question still remains unanswered.

Geltman[4] has used the value electron affinity (Li) = 0·384 eV., obtained by a quadratic extrapolation procedure with spectroscopic data on isoelectronic systems, for the threshold in his theoretical calculations of the continuous absorption coefficients of Li^-. This value does not agree with other estimated values (Ta-You Wu[5], 0·90 eV.; Moiseiwitsch[6], 0·74 eV.; and Holøien[7], 0·75 eV.).

The Ritz variational principle is a method frequently used for determining the electron affinity as the difference in potential energy between the ground-state of the atom and the ground-state of the negative ion. The limit to which a given choice of potential parameters makes the energy converge may be used as a criterion for the reliability of the results obtained.

However, such a calculation minimizing the energy in the Ritz variational procedure is difficult and tedious to carry out when applied to the four-electron Li^- ion, but in view of the facts mentioned above, a variational determination of electron affinity (Li) is very important. Fortunately, much progress is made by using an electronic computer in evaluating the matrix elements and solving the secular equation.

The purpose of this communication is to direct attention to results already obtained by variational calculation of the energy of H^- in the $(2s)^2\,{}^1S$ state using a 20-parameter function[8]. If we neglect in Li^- the inter-shell interaction and consider the K-shell as essentially at the nucleus, the variational procedure is identical with that for the $(2s)^2\,{}^1S$ state of H^-. By using the data quoted in Table 3, ref. 8, for H^-, the electron affinity $E\,(Li \rightarrow Li^-) = 0{\cdot}81$ eV. is obtained in good agreement with the estimated results[5–7] (1 eV. = 8066·0 cm.$^{-1}$). As an interesting comparison the data for helium quoted in the same table give $E(Be^+ \rightarrow Be) = 8{\cdot}12$ eV. (the observed value is 8·89 eV.).

Of course, when taking into account the repulsion of electrons with parallel spin by the penetration of the L-electrons into the charge distribution due to the K-electrons, the above electron affinity will be reduced; but by how much? It is hoped that a variational calculation applied to the ground-state of Li^- by using a 20 × 20 matrix built up from the same configurations for the L-electrons as in ref. 8 will answer this question. Further work along these lines is now in progress.

Improvement in the Magnetic Detecting Power of Iron-cored Search Coils

Slowly changing magnetic fields have usually been measured by means of search coils with iron or mumetal cores, connected either to fluxmeters or to galvanometers. In this communication the term 'coiled rod' is employed and means a straight ferromagnetic rod about which a detector-coil is wound. The sensitivity or detecting power of the coiled rod is usually defined as the total number of flux linkages of the winding produced in the coiled rod by a spatially uniform magnetic field of one oersted and is measured in Maxwell-turns per oersted. The advantage of mumetal over iron for the core of the coiled rod has been its high permeability in low magnetic fields, low electrical losses and low coercive force. Any further increase in sensitivity of coiled rods has been obtained either by lengthening the rod and so reducing its demagnetizing factor or by winding on more turns—the latter case being accompanied by a rapid increase in inductance and by increased resistance unless the diameter of the wire in the coil is correspondingly increased, which in turn affects the overall diameter.

It has been found that a very useful increase in sensitivity of a given coiled rod can be obtained by fitting permeable collector cones to the ends of the rod, the vertices of the cones facing towards the centre of the rod. So far as the experiments have proceeded, an eight-fold increase in sensitivity may be obtained. The increase in detecting power appears to be almost linear with diameter of cone up to the largest tested (1·5 times the length of the rod), the detecting power being increased by a factor K:

$$K = \left(1 + n\frac{D}{l}\right)$$

where n is about 6 for cone diameters (D) less than half the length (l) of the rod, and 5 for larger cones. A good working approximation for the whole range of D up to 1·5 l (and perhaps beyond) being:

$$K = \left(1 + 5{\cdot}4\frac{D}{l}\right)$$

It also appears that this increase in detecting power is accompanied by only a small increase in inductance, for example, in one case where K (detecting power) equalled 2·10, the corresponding inductance factor K_L was only 1·3. (K_L is defined similarly to K, that is, the ratio of the inductance of the coiled rod with collector cones to the inductance without cones.)

The expression above applies to coiled rods in which a uniform winding covers most (90 per cent) of the length of the rod; smaller increases only would be achieved where concentrated or asymmetric windings are employed, since it is known that fittings to the end of the rod affect the central flux in the rod to a much smaller extent than the flux towards the ends—they cause a more uniform distribution of flux over the whole length of the rod.

Cones have been used on mumetal rods of relatively large size (⅜ in. and greater diameters and a wide variety of lengths) and the axial depth of the cone has been arbitrarily fixed at 1 in. in order to provide a suitable fitting to the rod: each end of the rod fits into a recess in the cone and is rigidly secured by a steel screw. A typical design is illustrated in Fig. 1, in which the left-hand cone is shown withdrawn from the drilled and threaded rod-end. The material for the cones found most satisfactory has been machined mild steel, but cast steel has been successfully used in one case. Solid cones in the larger sizes cause a significant increase in the weight of the assembly; but hollow cones in various forms have been found to be useless as intensifiers. No investigation has been made on miniature coiled rods, where rod diameters may be ⅛ in. downwards to small-wire or rolled-strip sizes, to determine the corresponding practical axial depth of the cone for satisfactory use with such small detectors.

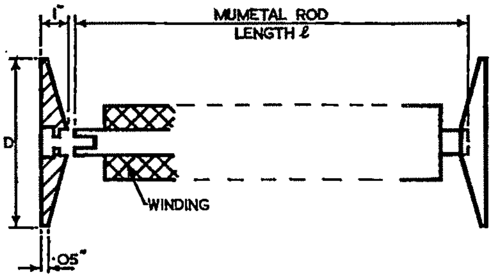

Fig. 1. Typical arrangement of mild steel collector cones on a coiled rod

Collector cones may be most useful where axial length of the coiled rod is restricted; where the weight, cost or resistance of the copper coils must be kept down but where the overall diameter is less important; or where cones of a diameter equal to or exceeding the length of rod may be employed. Where alternating magnetic fields are to be measured, precautions will have to be taken against losses due to eddy-currents in the cone as well as in the material of the rod. It would be interesting to investigate whether cones, in a suitable permeable material of high specific resistance, could be used with similar success in fluxgate detectors as intensifiers, since it is expected that an improvement in output signal voltage may be obtained similar to that described above for induction systems.

The mechanism of the increase is not fully understood. Since the distribution of flux along the rod is more uniform when cones are fitted, it may be deduced that the effect is caused by the spreading of the demagnetizing poles outwards from the ends of the rod on to the outside face of the cones. There is some evidence, however, that the magnetic field in part of the annular space between the cones but outside the rod (that is, the space occupied by the copper coils) is higher than the external field to be measured. This suggests that part of the function of the cones is to enhance the external field between them.

Effect of Humidity on the Spark Breakdown Voltage

THE influence of water vapour on the breakdown voltage of uniform field gaps has been investigated by Ritz[1]. He found that the breakdown voltage of a 1-cm. uniform field gap at 760 mm. mercury pressure in air increased by 2 per cent for a change in the partial pressure of water vapour from 10 to 25 mm. mercury. More recently, Köhrmann[2] has published results which indicate that the presence of water vapour at 10 mm. mercury raised the breakdown voltage by 2·7 per cent above that of dry air at 760 mm. mercury. Lewis[3] investigated the humidity effect for sphere gaps and quoted an increase of 0·13 per cent in voltage for each mm. mercury of water vapour. This value is rather low compared with the two other results and may be due to the fact that he used a gap of 0·4 cm. between 2-cm. spheres.

A uniform field gap was mounted within a glass cylinder which could be evacuated and gases admitted through a drying system. Water vapour could be added and its partial pressure measured. The d.c.-voltage source was stabilized to better than 1 part in 5,000 per hour. The breakdown voltage was determined by plotting the sparking-rate for a range of voltages above the minimum value and extrapolating the curve to a voltage corresponding to zero sparks per minute. The spark gap was unirradiated since it had been found that irradiation reduced the breakdown voltage of a plane gap by only about 0·1 per cent.

Measurements have been made under the following conditions: (1) plane electrodes, with a Bruce profile, in air at pressures of 760 mm. and 500 mm. mercury with water vapour and for gaps of 1 cm. and 2 cm. respectively; (2) plane electrodes in nitrogen at 760 mm. mercury with a mixture of 2 : 1 ethyl alcohol – water vapour and a 1-cm. gap; (3) spheres of 2-cm. diameter in air at 760 mm. mercury with water vapour and a 1-cm. gap.

The effect of humidity on the breakdown voltage in air and nitrogen is plotted in Fig. 1. The values for 2-cm. spheres appear to fit the same curve as those for plane electrodes. Two points are plotted which were obtained in moist laboratory air. These points also fit the curve reasonably well. Also shown in Fig. 1 are the results for the effect of ethyl alcohol – water vapour on the breakdown in nitrogen. These points lie below the curve for water and air; this is to be expected if the increase in voltage is solely an effect due to the water, since the partial pressure of water in the vapour mixture was 33 per cent of the total pressure of the vapour mixture. The breakdown

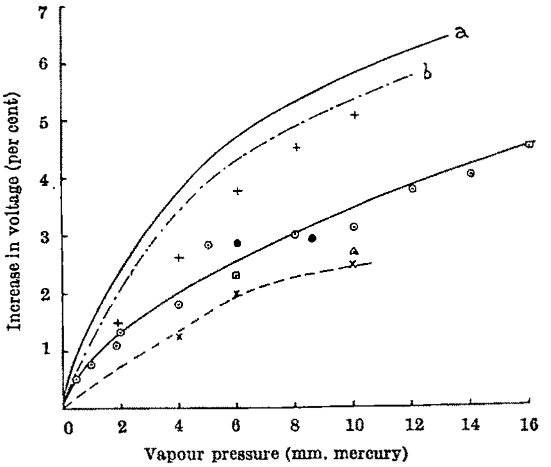

Fig. 1. Effect of vapour on breakdown voltage. (*a*) After Köhrmann (ref. 2) for 2-cm. gap at pressure of 500 mm. mercury; (*b*) calculated from measurements for a 1-cm. gap at 760 mm. mercury; +, air and water vapour, 2-cm. gap between plane electrodes at 500 mm. mercury; ⊙, air and water vapour, plane electrodes, 760 mm. mercury; ●, moist atmospheric air, plane electrodes, 760 mm. mercury; ⊡, air and water vapour, 1-cm. gap between spheres at 760 mm. mercury; △, after Köhrmann (ref. 2), plane electrodes at 760 mm. mercury; ×, nitrogen and ethyl alcohol – water vapour, plane electrodes at 760 mm. mercury

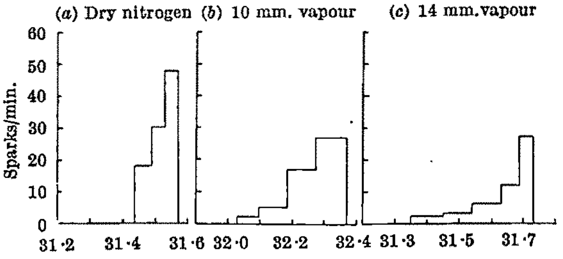
voltage in dry nitrogen was found to be 2·6 per cent higher than in air at 760 mm. mercury and 20° C. This difference could be explained by the lower value of α/p for nitrogen.

Referring to the results of Köhrmann for a 2-cm. gap in air at 500 mm. mercury it was noted that the effect of humidity was greater than for a 1-cm. gap at a pressure of 760 mm. mercury. These results are plotted in Fig. 1. Measurements made by us for a 2-cm. gap at 500 mm. mercury lie slightly below those of Köhrmann. The chain dotted line in Fig. 1 gives the values obtained at 760 mm. mercury for a 1-cm. gap normalized to 500 mm. mercury.

It was found that the rate of sparking was also a function of humidity. Several examples are plotted as histograms in Fig. 2 for increasing amounts of ethyl alcohol – water vapour in nitrogen. The rate of sparking for dry nitrogen increased from zero to 48 sparks/min. for a change in voltage of 0·13 kV., whereas with 10 mm. mercury vapour pressure the rate of sparking increased from zero to 25 sparks/min. for a change in voltage of 0·34 kV. When the vapour pressure was 14 mm. mercury the rate of sparking was approximately the same but the threshold voltage for sparking fell to a lower value. This threshold shifted to a higher voltage with continued sparking as shown in Fig. 2(*d*). Histogram (1) shows the first rate of sparking; after 20 min. sparking the histogram (2) shifted to a higher voltage and after 40 min. reached the still higher voltage of histogram (3). It was concluded that when the vapour pressure reached a certain value, condensation occurred on the electrodes and lowered the breakdown voltage. This layer of liquid was removed by sparking and the breakdown voltage then increased. Measurements with spheres showed a rather flat histogram for the rate of sparking, similar to Fig. 2(*d*), and accurate determination of the minimum breakdown voltage was more difficult.



(*d*) 21 mm. vapour

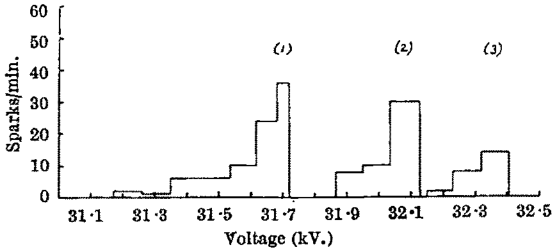


Fig. 2. Histograms of rate of sparking for different amounts of vapour

It may be concluded that the effect of water vapour is to increase the breakdown voltage by 3·5 per cent for 10 mm. mercury partial pressure of water vapour at 760 mm. mercury. The results are in general agreement with those of Köhrmann and Ritz for plane electrodes at 760 mm. mercury pressure in air. It is obviously necessary to correct for humidity when comparing values of breakdown voltage obtained under different conditions.

CHEMISTRY and GEOCHEMISTRY

Use of Approximate Wave Functions for Extrapolation to True Energy Values

A WAVE equation $H\varphi = E\varphi$ can be written for any trial function φ. Only if φ is equal to an eigenfunction ψ_n, however, does E have a constant value (E_n). In general, for any trial function, φ, there is a corresponding average energy, $E_{av.}$, defined by:

$$E_{av.} = \int\varphi^* H\varphi d\tau \Big/ \int\varphi^*\varphi d\tau$$

The variation principle shows that for the lowest state $E_{av.} \geqslant E_0$, and $E_{av.}$ is thus an upper bound to the true energy, E_0. No means is provided by the variation principle for the extrapolation to E_0 from a series of calculated values of $E_{av.}$

For an approximate function φ, the function $E = H\varphi/\varphi$ fluctuates about the mean value $E_{av.}$ with mean square deviation Δ given by:

$$\int\varphi^*\left(\frac{H\varphi}{\varphi} - E_{av.}\right)^2 \varphi d\tau \geqslant 0$$

Δ becomes equal to zero only when $E_{av.} = E_n$, a true eigenvalue. From a graph of Δ against $E_{av.}$, it might be possible to extrapolate back to $\Delta = 0$, where $E_{av.} = E_n$, and thus provide a useful means of estimating eigenvalues.

Calculations are presented here for two simple systems: (1) a single electron constrained to move in a ring in which the potential energy is a simple one-step function; (2) the helium atom in its ground-state.

(1) *Particle in a ring.* The ground-state eigenfunction is known in this case, and for the two regions of constant potential has the form:

$$a.\ \cos m\theta\left(-\frac{\pi}{6}<\theta<\frac{\pi}{6},\ V=0\right),$$

$$b.\ \cosh m'\theta\left(\frac{\pi}{6}<\theta<\frac{11\pi}{6},\ V=V_0\right)$$

θ being the cyclic co-ordinate. Successive approximations φ_n to the eigenfunction ψ_0 were obtained by taking inclusively the first n terms of the Fourier (cosine) series expansion of ψ_0. The corresponding values of Δ and $E_{av.}$ were readily calculated and are plotted together in Fig. 1.

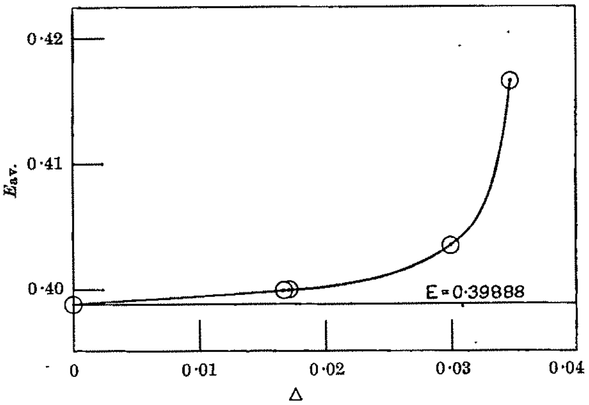

Fig. 1. Graph of $E_{av.}$ against Δ for a particle in a ring; the successive points are for 1-, 2-, 3- and 4-term Fourier (cosine) series. (Arbitrary units)

(2) *Ground-state helium atom.* The true ground-state energy is known spectroscopically. Approximate wave functions of the form (i) $\varphi = u(1)u(2)$, where $u(1)$ represents a hydrogen-like 1*s* function, and (ii) $\varphi = u_1(1)u_2(2) + u_1(2)u_2(1)$, were employed. The effective nuclear charges Z_1 and Z_2 were used as parameters in the usual way and the corresponding values of Δ and $E_{av.}$ calculated. These values are plotted together in Fig. 2.

The general form of the plots of Δ against $E_{av.}$ is similar in the two cases. Apparently, only when $E_{av.}$ is very close to E_0 is Δ likely to vary linearly with $(E_{av.} - E_0)$. Recent very detailed calculations by Kinoshita[1] confirm this. He finds that when $(E_{av.} - E_0)/E_0$ is in the range 0–0·000007, Δ varies linearly with $(E_{av.} - E_0)$.

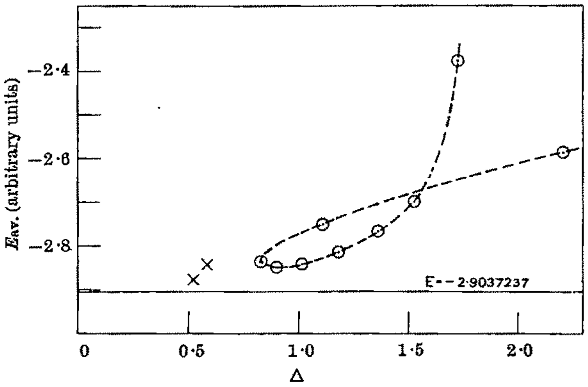

Fig. 2. Graph of $E_{av.}$ against Δ for the helium atom; ○, curve for function (i) with varying Z; ×, for function (ii) with varying Z_1 and Z_2

The wave functions used in the case of helium (ii) are relatively inflexible, and application of the variation method shows that the lowest possible energies for these types of function are bad approximations to E_0. In this case the minimum values of Δ and $E_{av.}$ do not coincide and $E_{av.}$ is not dependent only on Δ.

The construction of a set of trial functions by the inclusion of successive terms of a series expansion, having a complete orthogonal set as basis functions, as in case (i), leads to a single curve of Δ against $E_{av.}$. This type of trial function is to be preferred if Δ and $E_{av.}$ are to provide a useful extrapolation pair.

It appears likely that the inclusion of a not unreasonably large number of terms in such a trial function can enable a fair extrapolation to E_0 to be made.

We wish to thank the Harmsworth Trust of Merton College, the Department of Scientific and Industrial Research and the Gas Council for maintenance grants.

Determination of the Yields of Molecular Hydrogen Peroxide in the Radiolysis of Water labelled with Oxygen-18

The decomposition of water by the action of ionizing radiations can be represented by the overall expression[1,2]

$$H_2O \rightsquigarrow H,\ OH,\ H_2,\ H_2O_2 \qquad (1)$$

The relative extents of the radical (H, OH) and molecular yields (H_2, H_2O_2) have been determined for a number of radiations of different ionization densities. The molecular hydrogen yield ($G^W{}_{H_2}$) has been measured directly, in the presence of different solutes (for example, bromide, nitrite[3]). On the other hand, the molecular hydrogen peroxide yield ($G^W{}_{H_2O_2}$) in aqueous solutions irradiated in the presence of oxygen can ordinarily be measured only indirectly[4,5]. (G = molecules/100 eV.)

It is clear, however, that it should be possible to determine the yields of molecular hydrogen peroxide directly by using water enriched with $H_2{}^{18}O$. In these circumstances, only hydrogen peroxide which is formed from the isotopically labelled water, according to equation (1), will contain the oxygen isotope. Provided that the hydrogen peroxide thus formed is not decomposed by subsequent reactions, the molecular hydrogen peroxide yield can be obtained by isotopic analysis of the total hydrogen peroxide produced on irradiation. This analysis can be carried out by treatment of the irradiated aqueous solution with permanganate, which is known to liberate molecular oxygen derived solely from the hydrogen peroxide. Table 1 shows some results obtained from aqueous solutions enriched with $H_2{}^{18}O$ for two different solutes, namely, ethanol and lactic acid at *p*H 1·2 (0·1 *N* sulphuric acid) irradiated with cobalt-60 γ-rays and with 200 kV. X-rays. These two particu-

In quartzo-feldspathic compositions the (anhydrous) oxygen/glass-former ratio of 2·0 prohibits certain configurations requiring a higher proportion of oxygen. This constraint is lacking in the case of glasses of basic composition, and for them a wide range of structural alternatives is open, subject to control by the ruling physical conditions.

In substantially anhydrous glassy lavas of calc-alkaline type there is a progressive diminution in the number of glass-forming ions in unit volume with change in composition from dacite to basalt. The hydrated rocks corresponding in composition, but of intrusive origin, show oxygen-packing figures which exceed those of the anhydrous types by an amount that increases with the basicity. This effect (which may exceed 7 per cent) is attributed to the variable co-ordination state of aluminium and ferric iron, and reflects the effect of pressure as well as that of hydration. In any hydrated glass the water will be distributed between the different types of possible configuration in a manner reflecting the history of the glass. Several lines of evidence appear to point to a general tendency for the proportion of loosely bound water to increase with the total water content. Thus, for example, application of the Gladstone and Dale relationship shows an increase in the specific refractivity of water related to the rise in its concentration in the glass.

A full account of this work will be published elsewhere.

BIOCHEMISTRY and PHYSIOLOGY

Possible Role of Water in Collagen Structure

Although several investigations of the infra-red spectrum of collagen in the 2μ region have been reported[1], no comment appears to have been made on the fact that the absorption band at 5,150 cm.$^{-1}$, generally attributed to sorbed water, is dichroic. The extent of this dichroism is shown in Fig. 1 (above), obtained from kangaroo tail tendon in equilibrium with the laboratory atmosphere. In a further spectrum obtained after drying at 100° C. for 3 hr., shown in Fig. 1 (below), the absorption band at 5,150 cm.$^{-1}$ is virtually eliminated, thus confirming its assignment to sorbed water. Subsequent exposure to the laboratory atmosphere restored the dichroic absorption band at 5,150 cm.$^{-1}$.

It is possible that the observed dichroism is spurious in the sense that it is due to form dichroism rather than intrinsic dichroism; but this is unlikely since other fibres such as nylon and silk show no maxima in dichroism at this frequency and α-keratin and feather keratin only very minor maxima. If, as seems to be the case, the dichroism is intrinsic, it follows that hydrated collagen contains a proportion of water molecules which are preferentially oriented with respect to the polypeptide chains.

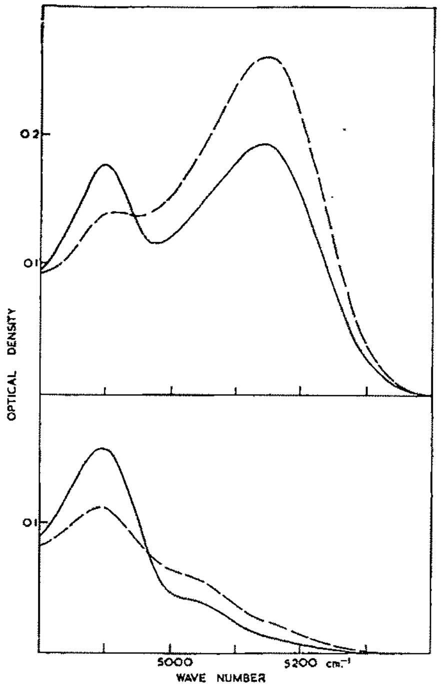

Fig. 1. Infra-red spectra of kangaroo tail tendon. Above, in equilibrium with the laboratory atmosphere; below, dried *in vacuo* at 100° C. for 3 hr. Full line, electric vector vibrating parallel to the tendon axis; broken line, electric vector vibrating perpendicular to the tendon axis

The absorption band at 5,150 cm.$^{-1}$ may be assigned to a combination of the antisymmetrical stretching and symmetrical deformation modes of the water molecule so that the associated transition moment is parallel to the line joining the two hydrogen atoms. The preferred orientation indicated by the perpendicular dichroism is therefore as shown in Fig. 2. From the magnitude of the dichroic ratio it is possible to estimate the minimum fraction of preferentially oriented water molecules[2], and this is found to be 0·18 for the spectrum of Fig. 1 (above).

The configuration of the polypeptide chain in collagen is believed to be such that the CO linkages are approximately normal to the chain axis and that a high proportion project outwards from the triple chain molecule and so are not available for intramolecular hydrogen bonding[3]. It is possible, therefore, that the oriented water molecules are linked to these groups through hydrogen bonds as shown schematically in Fig. 2.

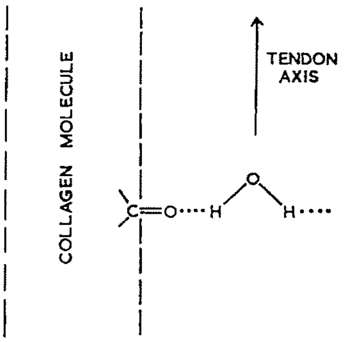

Fig. 2. Preferred orientation for water molecules in tendon deduced from the dichroism of the 5,150-cm.$^{-1}$ absorption band

An unusual feature of collagen is its high proportion of imino-acids, which do not have an N—H bond, and it may be significant that the fraction of oriented molecules calculated above is almost equal to the fraction of the total residues in which there is a CO but no NH bond.

Penicillin Derivatives of *p*-Aminobenzylpenicillin

THE formation of *p*-aminobenzylpenicillin was reported by Corse, Jones, Soper, Whitehead and Behrens[1]; but no material was isolated. Brewer and Johnson[2] later obtained partially purified material by using *p*-aminophenylacetic acid as precursor; but no details of yields or purity were given. The work reported here was carried out in order to obtain *p*-aminobenzylpenicillin for use as the parent compound of a series of derivatives. Tosoni, Glass and Goldsmith[3] have since reported the preparation of crystalline *p*-aminobenzylpenicillin by hydrogenation of *p*-nitrobenzylpenicillin and the preparation of certain N-acyl derivatives.

Fermentations were carried out using *Penicillium chrysogenum* 5120*c* (a sub-strain selected from 5120 *Wis*) and a peanut meal/lactose medium. *p*-Aminophenylacetamide was added at the rate of 0·05 per cent every 24 hr. Titres at 96 hr. were 1,000–1,200 μ/ml. by cup-plate assay. Paper chromatography using as solvent the top layer of the mixture butanol–ethanol–water, 40 : 10 : 50, indicated the formation of two principal penicillins and smaller amounts of two others as a result of the addition of the precursor (Fig. 1). The two principal penicillins (zones 3 and 4) were eluted from paper chromatograms and zone 3 identified as *p*-aminobenzylpenicillin. This penicillin was shown to contain a primary aromatic amino-group by diazotization and coupling with resorcinol. After acid hydrolysis, *p*-aminophenylacetic acid was identified on paper chromatograms and also estimated quantitatively. The penicillin from zone 4, on the other hand, although giving *p*-aminophenylacetic acid after acid hydrolysis, could not be diazotized except after acid hydrolysis, suggesting this penicillin to be a substituted *p*-aminobenzylpenicillin. The nature of penicillin 1 and 2 remains unknown.

The *p*-aminobenzylpenicillin was extracted by adjusting the clarified brew to *p*H 6·0 and then percolating through a column of granular charcoal as described by Abraham, Newton and Hale[4]. The column was eluted first with 15 per cent acetone, which removed considerable impurity, followed by 60 per cent acetone, which rapidly eluted all the penicillins. The fraction of this eluate containing penicillin was concentrated to small volume *in vacuo* and 9 vol. of acetone added to precipitate impurities. The supernatant, after centrifuging, was evaporated *in vacuo* to near dryness. This material was then dissolved in the butanol–ethanol–water chromatography solvent described above and chromatographed down a column of powdered cellulose and developed with the same solvent. The penicillins were eluted separately in the order in which they ran on paper strip chromatograms. The eluate fractions containing the *p*-aminobenzylpenicillin were combined and extracted with water, which was then freeze dried. The pale yellow solid obtained assayed at 800 μ/mgm. by cup-plate assay using benzylpenicillin as standard; pure *p*-aminobenzylpenicillin obtained by Tosoni *et al.*[3] assayed at 1,100 μ/ml., indicating the material described here to have been 73 per cent pure. Assay of the latter material by the hydroxylamine method[5] gave a figure of 75 per cent purity.

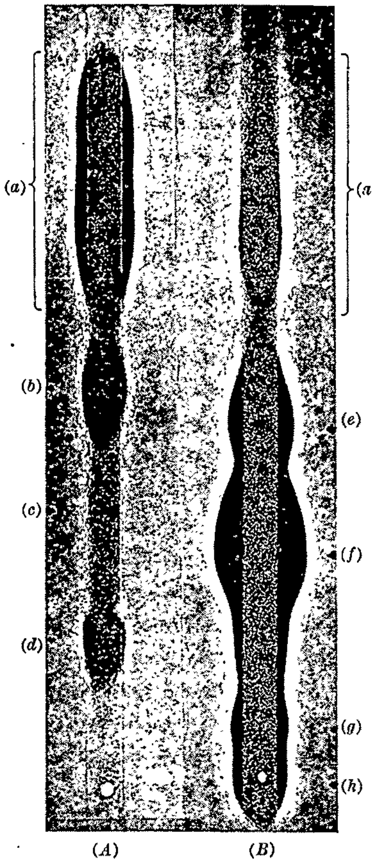

Fig. 1. Paper chromatography of harvest fermentation brew. *A*, No precursor added; *B*, *p*-aminophenylacetamide added, 0·05 per cent every 24 hr. Solvent, butanol–ethanol–water, 40 : 10 : 50, top layer. Chromatograms developed on agar plate seeded with *B. subtilis*. *a*, Penicillins *K*, FH_2, *F*, *G*; *b*, penicillin *X*; *c* and *d*, unidentified penicillin; *e*, penicillin 4; *f*, penicillin 3; *g*, penicillin 2; *h*, penicillin 1.

During the course of the extraction a white crystalline solid separated out on cooling, which, after recrystallization, was identified as the monohydrate of *p*-acetamidophenylacetamide (by elementary analysis and mixed m.p. with an authentic specimen prepared by acetylation of *p*-aminophenylacetamide). The formation of this material during the fermentation suggested that penicillin 4, which appeared to be a substituted *p*-aminobenzylpenicillin, might be *p*-acetamidobenzylpenicillin. Comparison of this penicillin 4 with an authentic preparation of *p*-acetamidobenzylpenicillin prepared from the *p*-aminobenzylpenicillin showed them to be indistinguishable on paper chromatograms and in respect of their antibacterial spectra.

The *p*-aminobenzylpenicillin has been converted into a series of N-derivatives[6] by treatment with reactive halogen compounds such as carboxylic acid halides, 2 : 4-dinitrofluorobenzene and *p*-toluenesulphonyl chloride, following the method of Newton and Abraham[7] for the preparation of derivatives of cephalosporin N. It is hoped to publish further details of these experiments, together with the results of the antibacterial activity of the derivatives, elsewhere, at a later date.

Nucleotide Metabolism in Cardiac Activity

In a previous study on the nucleotide metabolism of cardiac muscle[1], the changes of adenosine triphosphate were investigated during systole and diastole. Using the Cohn and Carter method of analysis[2] on a 'Dowex-1' column, the nucleotides were separated and determined quantitatively by ultra-violet absorption spectrophotometry. During the studies on the extracts of hearts frozen in systole by an acetone–dry ice mixture, a substance appeared as a new peak in the chromatogram, which seemed to be an adenine nucleotide with more nitrogens than could be accounted for. This was called nucleotide *H*.

In spite of the recent results obtained by Mommaerts[3] and Fleckenstein *et al.*[4] it was decided to re-investigate this problem, with special emphasis on nucleotide *H*.

Hearts of dogs were excised rapidly and dropped either into cold isotonic potassium chloride to stop them in diastole, or into liquid air to freeze them in systole. The hearts were then rapidly homogenized in a Waring blendor with 2·5 vol. 0·5 *N* perchloric acid, centrifuged, and the supernate neutralized to *p*H 8 with potassium hydroxide. In all these steps, the temperature was kept below 5° C. After removing the potassium perchlorate by filtration, an aliquot corresponding to about 4 gm. of the original muscle was placed on a 'Dowex-1' column in the chloride cycle, with a bed volume of either 5 or 7 ml. Elution was carried out according to Cohn and Carter[2] except that 0·005 *N*, instead of 0·003 *N*, hydrochloric acid was used, and this was used as the first eluant.

With this system, the results previously obtained[1] were verified. With 0·005 *N* hydrochloric as eluant, adenine was eluted at 2–4 bed volumes and inosinic acid at 15–17 bed volumes. A long trailing peak was eluted at about 50–100 bed volumes, and this was identified as adenosine diphosphate. Usually, elution was stopped after 40 bed volumes of 0·005 *N* hydrochloric acid and the next eluant started. In diastolic hearts no further peaks were obtained with the first eluant; but in systolic hearts another peak came off the column at 22–27 bed volumes, which corresponded to the previously identified nucleotide *H*. This fraction was collected, neutralized to *p*H 7, and concentrated *in vacuo* at a temperature below 50° C. On phosphorus analysis[5], one organic and usually one inorganic phosphorus were obtained per mole adenine, determined spectrophotometrically. Occasionally more than one inorganic phosphorus was obtained. On paper chromatography, using Hanes and Isherwood's[6] method to determine the phosphorus spots, and Magasanik's[7] method to determine the purine spots, a phosphorus spot was always associated with the purine spot, at an R_F value that corresponded to adenylic acid. On mixing some of the unknown with authentic adenylic acid, the purine spots could not be separated on paper.

Furthermore, on paper chromatography there were always two ninhydrin spots identified as aspartic and glutamic acids, with occasionally a third one identified as alanine. Again, on mixing the unknown with authentic glutamic and aspartic acids, no separation occurred on paper.

On rechromatography on 'Dowex-1', or following the precipitation of the nucleotides with mercuric acetate[8], the two amino-acids and the adenylic acid spots were always present, and yet they never chromatographed as one unit on paper. Using the solvent system, *iso*butyric acid/ammonia/water, 66 : 1 : 33, the R_F value for nucleotide *H* was 0·51, adenylic acid 0·51, glutamic acid 0·45, and aspartic acid 0·35. A mixture of adenylic, aspartic and glutamic acids acted in all respects like nucleotide *H*.

Thus, in conclusion, the previously named nucleotide *H* is only an artefact made up of adenylic, aspartic and glutamic acids. On the anion exchange resin, 'Dowex-1', it happened that these three compounds are eluted from the column at the same rate, and are precipitated together by mercuric acetate.

The reason why the two amino-acids appear only in systolic hearts remains to be investigated.

Biochemical Differentiation of Group *A* and 'Human *C*' *Streptococci*

MOST *Streptococci* are satisfactorily differentiated by relatively simple biochemical methods. Among the exceptions are *Streptococcus pyogenes* (group *A*) and the 'Human *C*' *Streptococcus* (group *C*), which are differentiated with reliability only by Lancefield's serological technique[1]. Wilson and Rosenblum[2] showed that 477 cultures of *S. pyogenes* failed to multiply in raw milk sterilized with ethylene oxide while 31 cultures of group *C Streptococci*, of which at least 11 were 'Human *C*', always grew well in this medium. Recently, Levinson and Frank[3] have published a method utilizing bacitracin for the differentiation of group *A Streptococci*. Approximately 10 per cent of their 67 group *C* strains were not differentiated. They mention the possibility of resistant group *A* strains emerging as a result of the clinical use of bacitracin. Since *S. pyogenes* and 'Human *C*' *Streptococci* are not readily distinguished biochemically by any single test or combinations of such tests[1,4] in present use, a medium and method of differentiating them are of interest.

A medium for this purpose is prepared as follows. 5 ml. of commercial rennet extract is added to 1 litre of fresh, antibiotic-free, raw milk tempered to 40° C. The resulting curd is cut into cubes, and the whey is strained through a cheese-cloth, after which it is centrifuged for a few minutes. Clear whey is removed from the sediment and milk-fat with an aspirator and filtered twice through Whatman No. 42 filter paper, then through a Selas 02 bacteriological filter candle previously autoclaved after being charged with 0·1 *N* hydrochloric acid. The sterile medium is dispensed into sterile test-tubes and incubated for 24 hr. at 37° C. as a sterility check. Tubes showing turbidity are discarded.

Several precautions must be observed in the preparation and care of the test medium. The milk must be raw (unheated) as *S. pyogenes* is able to multiply in heated milk. The raw milk must be free from antibiotics as residual antibiotic resulting from mastitis therapy prevents the growth of 'Human *C*' *Streptococci* in milk. Incubation of the test medium after sterilization is necessary since results are based on turbidity. Prepared medium should be stored in the dark since it is known that exposure to light for extended periods of time eventually allows a slight growth of *S. pyogenes* in raw milk serum. It is necessary to filter the medium twice through filter paper before sterilization or the medium will plug the filter candle before any quantity is obtained.

To differentiate between cultures of *S. pyogenes* and 'Human *C*' a loopful of culture is inoculated into tubes of the sterile, raw milk serum medium. The tubes are incubated for 24 hr. at 37° C. Growth, as shown by turbidity, indicates the presence of 'Human *C*' *Streptococci*. Lack of growth (no turbidity) indicates the presence of *S. pyogenes*.

Nine cultures[5], six of *S. pyogenes* and three of 'Human *C*' *Streptococci*, were grown in meat-infusion broth. They were transferred daily for several weeks and then kept one month in broth without transfer. For the remainder of the test period of six months these cultures were transferred weekly, except for the last week, when they were again transferred daily. The six strains of *S. pyogenes* never multiplied in the raw milk serum medium, as shown in Table 1. This was true when the cultures were young (18 hr.), old (1 month), and transferred daily, weekly or sporadically. The 'Human *C*' cultures always grew in the test medium under the same conditions, attaining counts of greater than 200 million per ml.

Table 1. THE GROWTH OF *Streptococcus pyogenes* AND 'HUMAN *C*' STREPTOCOCCI SUBCULTURED PERIODICALLY IN RAW MILK SERUM MEDIUM

Culture number and group		Subcultured									
		Daily 1	Daily 2	Weekly 1	Weekly 2	Monthly 1	Monthly 2	Monthly 3	Sporadically 1	Sporadically 2	Sporadically 3
*C*203*S*	(*A*)	–	–	–	–	–	–	–	–	–	–
*A*4	(*A*)	–	–	–	–	–	–	–	–	–	–
*A*6	(*A*)	–	–	–	–	–	–	–	–	–	–
*A*8	(*A*)	–	–	–	–	–	–	–	–	–	–
*A*9	(*A*)	–	–	–	–	–	–	–	–	–	–
*A*11	(*A*)	–	–	–	–	–	–	–	–	–	–
*C*519	(*C*)	+	+	+	+	+	+	+	+	+	+
*C*556	(*C*)	+	+	+	+	+	+	+	+	+	+
7078	(*C*)	+	+	+	+	+	+	+	+	+	+

–, No growth. +, Profuse growth.

Others[2] have shown that the property of growth or lack of growth in the raw milk serum medium characterizes many more strains of *S. pyogenes* and 'Human *C*' *Streptococci* than the nine reported here. The procedure previously used required a streak plate after culture in the differentiating medium because of the opacity of the differentiating medium. The medium described here was prepared in the course of another investigation[6] and the necessary testing of a large number of cultures was not possible. It is felt that the simplicity of the turbidimetric method and its potential value in the biochemical scheme of differentiation of *Streptococci* justify a report based on a limited number of cultures.

Effect of Insulin and Phenazine Methosulphate on Pathways of Glucose Catabolism in the Mammary Gland of the Rat

THERE is considerable evidence that a large part of the glucose catabolism of the lactating mammary gland of the rat occurs by way of the pentose phosphate pathway[1]. The effect of insulin on the relationship between glucose utilization and fatty acid synthesis has recently been investigated by Abraham *et al.*[2], who have shown that the addition of insulin to mammary gland slices from lactating rats caused an increased production of carbon dioxide labelled with carbon-14 from (1-^{14}C)glucose and an increased incorporation of glucose carbon into fatty acids.

There is also growing evidence that one of the factors controlling the activity of the pentose phosphate pathway in many tissues is the supply of

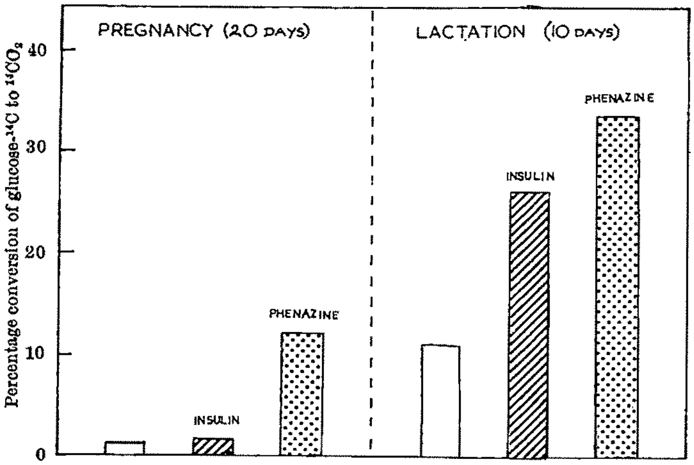

Fig. 1. Effect of insulin and phenazine methosulphate on the conversion of (1-^{14}C)glucose to labelled carbon dioxide by mammary gland slices from pregnant and lactating rats. 500 mgm. mammary gland slices incubated with 4·5 ml. Krebs–Ringer bicarbonate solution and 20 mgm. glucose containing 0·2 μc. (1-^{14}C)glucose. Gas phase oxygen + carbon dioxide (95 : 5). Incubation period 90 min. at 38° C. Additions to flasks: 1 I.U. insulin or phenazine methosulphate (final concentration 1×10^{-4} *M*)

oxidized triphosphopyridine nucleotide[3-5]. In the lactating mammary gland, as in most animal tissues, triphosphopyridine nucleotide is present almost exclusively in the reduced form[6]. It seemed possible that the stimulation of a reductive synthetic process utilizing reduced triphosphopyridine nucleotide, such as fatty acid synthesis, could lead to a parallel increase in the activity of the pentose phosphate pathway. One of the sites of action of insulin in the mammary gland might therefore be localized in the process of fatty-acid synthesis, the stimulation of which could produce a secondary effect on the activity of the pentose phosphate pathway. Evidence for this has been obtained from a study of the effect of insulin and phenazine methosulphate on the oxidation of either (1-^{14}C)glucose or (6-^{14}C)glucose by rat mammary gland slices at different functional stages. The results of some of these experiments are summarized in Fig. 1.

The marked difference in the effect of insulin on the oxidation of (1-^{14}C)glucose by tissue slices from pregnant and lactating rats can be seen in the histogram. Insulin has very little effect on the low rate of production of carbon dioxide labelled with carbon-14 by mammary tissue from pregnant rats, but causes a doubling of the rate of formation of labelled carbon dioxide by slices of lactating mammary gland. It seems probable that this difference between the glands from pregnant and lactating animals is related to their fat synthesizing capacity. Whereas the lactating gland has been shown to respond to treatment with insulin by an increase in the rate of formation of fatty acids[2,7], no such effect can be demonstrated in the mammary gland from pregnant rats.

The addition of phenazine methosulphate to slices of lactating mammary gland results in a stimulation of formation of labelled carbon dioxide from (1-^{14}C)-glucose as great as that found with insulin and, it should be noted, it produces an even more striking effect, a ten-fold increase, in slices of mammary tissue from pregnant animals. A series of other artificial electron acceptors produced similar effects.

The oxidation of carbon-6 of glucose is increased, but to a very much lesser extent, by the presence of phenazine methosulphate; insulin caused a pronounced decrease in the formation of labelled carbon dioxide from (6-^{14}C)glucose by mammary tissue from lactating rats. The increased production of labelled carbon dioxide from (1-^{14}C)glucose may thus be attributed mainly to an increased formation of labelled carbon dioxide by way of the first two, triphosphopyridine nucleotide-linked, steps of the pentose phosphate pathway.

It is suggested that the effect of phenazine methosulphate and of insulin in increasing the oxidation of glucose by way of the pentose phosphate pathway is mediated by increasing the rate of re-oxidation of reduced triphosphopyridine nucleotide; in the case of phenazine methosulphate by acting as an electron acceptor and of insulin by promoting the utilization of the hydrogens in the synthesis of long-chain fatty acids (see Hele, ref. 8).

This work will be reported in detail elsewhere.

The crystalline insulin, free from hyperglycæmic-glycogenolytic factor, used in these experiments was kindly given by Dr. Hallas-Møller, Novo Terapeutisk Laboratorium.

Partition of Selenium-75 in the Intracellular Particulate Matter of Rat Liver

In the mammalian organism there is an apparent fixation of trace amounts of selenium in various tissue proteins. This has been demonstrated in studies of proteins from blood[1,2], liver[3,4] and leukocytes[5]. Hydrolysates of purified protein[4] of dog liver labelled with selenium-75 contain at least three different compounds with radioselenium. These compounds behaved like amino-acids in ion-exchange and precipitation studies and appeared on paper chromatograms in the (*a*) cystine and selenocystine, (*b*) methionine and selenomethionine, and (*c*) leucine areas. Neither the metabolic pathway or process by which inorganic selenium is converted to organo-selenium nor the biological function of selenium is known. Since time-distribution studies[6] have revealed that the highest average concentration of 19 per cent of the dose was found in the liver, and since the liver is generally considered the main site of protein synthesis, we have undertaken to study the distribution of selenium-75 in the intracellular particulate matter of rat liver.

Three adult male rats were injected subcutaneously with a single dose of selenious acid labelled with selenium-75 which contained approximately 0·225 mc.

Table 1. DISTRIBUTION OF SELENIUM-75 IN RAT LIVER CELLS (Values represent average of three experiments)

	Total selenium-75		Protein-bound selenium-75*	
	Percentage uptake	Activity per mgm. total nitrogen	Percentage uptake	Activity per mgm. total nitrogen
Homogenate	100·0†	1·00‡	80·3 ± 2·3	1·00‡
Nuclear fraction	2·7 ± 0·4	0·41 ± 0·04	87·4 ± 11·5	0·44 ± 0·03
Mitochondria	31·0 ± 1·6	0·66 ± 0·07	91·7 ± 2·2	0·76 ± 0·08
Microsomes	8·9 ± 1·7	1·26 ± 0·32	88·7 ± 5·1	1·39 ± 0·32
Soluble fraction	54·6 ± 1·1	1·47 ± 0·09	54·6 ± 3·7	1·00 ± 0·10

* Material insoluble in trichloracetic acid.

† 1 ml. homogenate = 23,673 c.p.m. (Exp. 1); 28,372 c.p.m. (Exp. 2); 28,842 c.p.m. (Exp. 3).

‡ Whole liver homogenate, 1·00.

of radioselenium and 0·03 mgm. of selenium per rat. The fasted animals were killed 24 hr. later, and the livers were removed, weighed and perfused with and homogenized in cold 0·44 *M* sucrose. Fractionation of the homogenate was performed essentially by the method of Dounce *et al.*[7]. Radioactivity was determined on aliquots of the homogenate and the nuclear, mitochondrial, microsomal and supernatant fractions. The nuclear and the mitochondrial fractions were washed three and two times respectively with 0·44 *M* sucrose. Total nitrogen was determined by the micro-Kjeldahl method of Clark[8]. Protein-bound selenium was determined by the standard tricholracetic method.

Results revealed that about one-half and one-third of the total selenium-75 activity, expressed as a percentage of the homogenate, were found in the soluble and mitochondrial fractions respectively, with smaller amounts in the remaining fractions. Total activity recovered was 97·2 ± 0·5 per cent, and total nitrogen recovery was 98·9 ± 4·2 per cent. The uptake of selenium-75 per mgm. of total nitrogen was found in decreasing amounts in the soluble, microsomal, mitochondrial and nuclear fractions respectively. The amount of selenium-75 precipitated with trichloracetic acid in all the fractions ranged from 70·1 to 96·2 per cent, except in the soluble fraction, where 48·5–57·9 per cent was found. Expressing the values on the protein-bound selenium basis, it was found that the microsomes had the highest values while the nuclear fraction had the lowest.

The preliminary studies on liver cell fractionation showed a wide but varied distribution of selenium-75 in the particulate matter. Expressed as protein-bound selenium-75 per mgm. nitrogen, the microsomes appeared to be the principal protein intracellular site of the uptake of radioselenium. However, the total amounts of selenium-75 activity in the soluble and mitochondrial fractions, which represent protein and non-protein radioselenium, respectively, were greater than those found in the microsomal and nuclear fractions.

Since fixation of selenium-75 in protein was found in all fractions studied, it appears that this phenomenon is not unique for any particular fraction. These findings are consistent with previous observations that trace amounts of selenium are fixed in a variety of proteins. On the other hand, the fact that all subcellular structures are able to fix selenium-75 in proteins may mean that all the particulate matter of liver cells plays a part in the fixation of selenium.

Action of Nicotinamide on Acetoacetate Metabolism of Liver Homogenates of Normal and Alloxanized Rats

THE results of *in vivo* studies show that nicotinamide has a ketogenic effect on alloxanized rats[1,2]. On the other hand, Villa and Dioguardi[3] observed that nicotinamide considerably increases the oxygen consumption of liver homogenates of normal rats in a medium containing sodium acetoacetate, and they suggested that this effect is the result of stimulation of the keto-oxidative system. Recently, we observed[4] that the rate of oxygen uptake of liver homogenates of alloxanized rats rises after the addition of ethyl acetoacetate; but the oxygen consumption is not relatively higher after the addition of nicotinamide.

In the present study two series of tests were made in order to determine the effect of nicotinamide on oxygen and acetoacetate uptake of liver homogenates of alloxanized rats in media containing sodium acetoacetate in a Warburg respirometer at 30·4° C. We found: (1) The rate of oxygen uptake of the liver homogenate rises after the addition of sodium acetoacetate. Nicotinamide induces a further increase (Table 1). (2) Using liver homogenates from 25 rats under the same conditions, no significant difference in amount of acetoacetate (measured by two

Table 1

Homogenates	Media	Oxygen uptake mm.^{3}/hr. ± S.E.
Liver 100 mgm.	Buffer (phosphate *p*H 7·4)	23·46 ± 1·7
	Buffer + sodium acetoacetate (18 mgm. approximately)	36·25 ± 1·9
	Buffer + sodium acetoacetate + nicotinamide (2 mgm.)	52·14 ± 3·0

Table 2

Homogenates	Media	Amount of total acetone (in mgm.) after an incubation of 4 hr. ± S.E.
Liver 200 mgm.	Buffer + sodium acetoacetate (18 mgm. approximately)	7·54 ± 0·21
	Buffer + sodium acetoacetate + nicotinamide (2 mgm.)	7·48 ± 0·17

different methods) (ref. 5 and unpublished data of the authors, by a colorimetric method, based on Gerhart's ferric chloride reaction) was found after 4 hr. between experiments with and without added nicotinamide (Table 2).

We conclude that addition of nicotinamide to liver homogenates of alloxanized rats, containing sodium acetoacetate as substrate, increases the oxygen consumption in some conditions without any significant utilization of the acetoacetate.

Sparing Effect of Serum from Mice treated with Endotoxin upon Certain Murine Virus Diseases

Bacterial endotoxin has a complex pharmacological action upon animals ; this includes a febrile response beginning about 2 hr. after its intravenous or intraperitoneal inoculation. Blood serum from dogs[1] and rabbits[2] 2 hr. after the inoculation of endotoxin contains a pyrogen distinct from endotoxin[3,4]. It has been termed 'endogenous pyrogen' and is believed to be produced by damaged cells, notably leucocytes. Indeed, it has been suggested that cells damaged in ways other than by endotoxin produce endogenous pyrogen and that endogenous pyrogen may be the factor common to fevers of diverse etiology[4].

It has been shown that mice treated with endotoxin have increased susceptibility to the pathogenic action of ectromelia virus[5]. The facts mentioned above with regard to endogenous pyrogen suggested that the inoculation of serum of mice bled 2 hr. after injection with endotoxin might increase the susceptibility of mice to ectromelia virus in the same way as the inoculation of endotoxin. This possibility was tested as follows. Adult mice (strain *VS*) were bled 1$\frac{3}{4}$–2$\frac{1}{4}$ hr. after inoculation of endotoxin present in growth filtrates of *Salmonella typhimurium*[6]. Normal serum was prepared from comparable mice uninoculated with endotoxin. Each serum was inoculated intraperitoneally into 20 weanling mice (0·4 ml.), and 3 hr. afterwards both groups of mice, together with a group of 20 control mice, were inoculated intraperitoneally with 5 *LD*50 of ectromelia virus. A similar experiment in which the sera had been heated at 56° C. for $\frac{1}{2}$ hr. was also carried out.

Table 1

Source of serum	Unheated serum: Survival-rate 7 days after virus inoculation. Mice surviving/Mice in group	Unheated serum: Probability that difference is due to chance χ^2	P	Heated serum: Survival-rate 8 days after virus inoculation. Mice surviving/Mice in group	Heated serum: Probability that difference is due to chance χ^2	P
Endotoxin-treated mice	18/20	10·7	0·001	13/20	6·5	0·01
Normal mice	7/20			4/20		
Controls (no serum)	9/20			8/19		

The proportion of mice in each group which survived on the first day on which the mortality of the controls exceeded 50 per cent is shown in Table 1. It will be seen that significantly more of the mice survived which had received serum from endotoxin-treated mice, whether heated or unheated. The result was opposite to that expected, and suggested the presence in serum from mice treated with endotoxin of a substance which raises the resistance of mice to ectromelia virus. These experiments have been repeated with similar results.

Since the method of production of the protective serum has no obvious connexion with ectromelia, we considered that it might act in a similar way with other infections. We therefore studied its effect upon the mortality-rate which results from the dual infection of mice with *E. coccoides* and mouse hepatitis virus (*MHV* 1). It will be recalled that whereas *E. coccoides* is a harmless blood parasite of mice and mouse hepatitis virus causes a mild non-fatal hepatitis, infection of mice with *E. coccoides* followed by mouse hepatitis virus results in an acute hepatitis which is fatal in weanling mice[7,8].

Groups of 50 weanling mice were inoculated intraperitoneally with *E. coccoides* (0·2 ml. of blood containing the parasite diluted 10^{-6}) 24 hr. before the intraperitoneal inoculation of 10 *LD*50 of virus. Some groups were kept as controls, others were inoculated intraperitoneally with sera 3 hr. before the virus as in the previous experiments but the dose of serum was reduced to 0·2 ml. The results are shown in Table 2.

The proportion of survivors is higher in mice which received serum from mice reacting to endotoxin, whether fresh or heated, than in mice which received normal serum. The higher survival-rate in mice which received normal serum compared with that of the control mice which received no serum conformed to previous experience[9].

Preliminary experiments indicate that serum from rabbits reacting to endotoxin increases the resistance of mice to ectromelia ; rabbit serum has not yet been tested against *E. coccoides–MVH* 1 infection.

Table 2

Source of serum	Unheated serum: Survival-rate : Mice surviving / Mice in group	Unheated serum: Probability that difference is due to chance χ^2	P	Heated serum: Survival-rate : Mice surviving / Mice in group	Heated serum: Probability that difference is due to chance χ^2	P	Total: Survival-rate : Mice surviving / Mice in group	Total: Probability that difference is due to chance χ^2	P
Endotoxin-treated mice	36/49	5·2	$< 0·05$	35/49	3·5	$< 0·1$	71/98	9·5	$< 0·01$
Normal mice	24/49			25/49			49/98		
Controls (no serum)	16/48			13/49			29/97		

These results suggest the possibility that serum from animals reacting to endotoxin might show a similar protective effect against a wide variety of infections. We also consider that the protective substance may be present in the blood serum of animals reacting to toxic agents other than endotoxin, by analogy with the idea that endogenous pyrogen is produced by tissues damaged by diverse pyrogenic agents. These possibilities and the nature of the protective substance are being studied.

Isolation of a Lipopolysaccharide from *Vibrio fetus*

Vibrio fetus infection is an important cause of infertility in cattle throughout the world. Little is known of the pathogenesis of this disease, partly because of the difficulty of obtaining massive growth of the vibrio *in vitro*. The recent development in this laboratory of a method of obtaining satisfactory yields of cells[1] has enabled fractionation studies on *Vibrio fetus* to be undertaken.

A toxic lipopolysaccharide has been isolated by the phenol extraction method of Westphal *et al.*[2]. Before extraction, flagella were detached by shaking the cells in sterile saline for 1 hr.[3], and surface antigens removed by treatment with 0·5 *M* potassium thiocyanate for 72 hr. at 37° C.[4]. The lipopolysaccharide was dialysed at 0° C. to remove all traces of phenol and gave a viscid, opalescent solution. An apparently identical lipopolysaccharide has been recovered from both smooth and rough forms of *Vibrio fetus*.

The substance conforms to the general characteristics of the lipopolysaccharides of Gram-negative bacteria in being toxic, pyrogenic and antigenic. Examination of a sample of the lipopolysaccharide by Dische's sulphuric acid – cysteine method[5] revealed the presence of an aldoheptose component. The absorption spectrum in a Hilger 'Uvispek' showed a curve suggestive of a lipopolysaccharide with a minimum contamination with nucleic acid. Hydrolysis with 1 per cent (v/v) acetic acid at 100° C. for 3 hr. yielded a small amount of a chloroform-soluble lipid.

The toxicity and pyrogenicity is greatly enhanced by heating the solution at 80° C. for 5 min. Rabbits are particularly susceptible, and deaths have occurred at the dose-level of 400 μgm./kgm. administered intravenously. The lethal dose is reduced to 40 μgm./kgm. rabbit by pre-heating. Nevertheless, rabbits withstand intramuscular injections of 10 mgm. of unheated lipopolysaccharide solution without apparent ill-effects. Mice are less susceptible, and the lethal dose is in the vicinity of 2 mgm. administered intravenously.

A febrile response in rabbits may be elicited with as little as 4 μgm./kgm., and the pyrogenic dose is reduced by heat treatment to as low as 0·005 μgm./kgm. Increases in temperature of 3–7·9° F. have been recorded. The temperature rises sharply within the first hour, reaches a peak in the majority of cases in 3 hr. and slowly falls to normal. The return to normal may take more than 24 hr.

Lipopolysaccharides, from both smooth and rough variants, are adsorbed on to human 'O' erythrocytes and give hæmagglutination when tested against homologous *Vibrio fetus* whole-cell rabbit antisera. The use of *Vibrio fetus* lipopolysaccharide in such a test may be of value in providing earlier and more accurate diagnosis of the disease in cattle. The lipopolysaccharide is a suitable antigen in the 50 per cent-hæmolysis-unit complement-fixation test using *Vibrio* antisera from rabbits. Further serological studies with this lipopolysaccharide are being undertaken.

I wish to thank Mr. R. V. S. Bain and Dr. K. Knox for their help and advice in these studies.

Effect of Lytic Enzyme from *Bacillus circulans* and Chitinase from *Streptomyces* sp. on *Aspergillus oryzae*

THE enzyme contained in a culture fluid of *Bacillus circulans* has been shown to exert lytic activity towards *Aspergillus oryzae* and that a polymer of melibiose was liberated from the cell wall. However, the cell wall was not completely lysed by the enzyme owing to the large amount of chitin present. During the search for enzymes causing lysis of fungal cells, it was found that a mixed preparation of chitinase and lytic enzyme exerted strong lytic activity on the cell wall of *A. oryzae*.

In this communication some observations pertaining to the action of chitinase and lytic enzyme, and to the fine structure of the cell wall are given.

The cell wall and the lytic enzyme were prepared by methods previously described. The crude chitinase was used as a chitinase preparation[2]. The mycelia of *A. oryzae* which had been previously shaken in the peptone–starch medium for 12 hr. at 30° C. was used as intact cells. Washed living mycelia and the cell wall were suspended in the various enzyme solutions using *tris*-buffer *M*/50, *p*H 6·8 and were incubated at 37° C. Turbidity of the suspension was determined by the Itô Beckman type spectrophotometer at 10-min. intervals over a period of 1½ hr.

As shown in Fig. 1, the lysis progressed more rapidly when the lytic enzyme was added together with the chitinase than when added alone. Moreover, after 2 hr. had elapsed scarcely any cell wall and intact cells could be detected by either a phase-contrast microscope or an electron microscope.

40 mgm. of the cell wall were suspended in a solution consisting of 20 ml. of the lytic enzyme solution, 20 ml. of the chitinase solution or 20 ml. of the

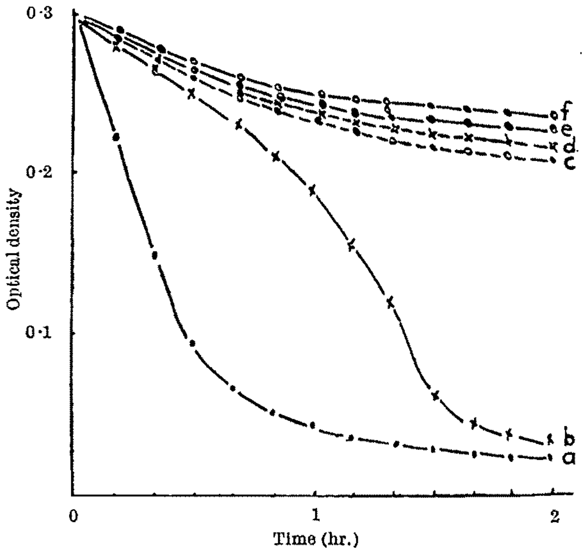

Fig. 1. Action of lytic enzyme and chitinase on the cell wall and on intact cells. Washed intact cells and cell wall were suspended in enzyme solutions (*tris*-buffer *M*/50, *p*H 6·8), and were incubated at 37° C. *a*, Cell wall (enzymes: lytic enzyme + chitinase); *b*, intact cells (enzymes: same as *a*); *c*, cell wall (enzyme: chitinase); *d*, cell wall (enzyme: lytic); *e*, intact cells (enzyme: lytic); *f*, intact cells (enzyme: chitinase)

chitinase and the lytic enzyme solution. About 5-ml. portions of this mixture were sampled at 30-min. intervals, and hexose and hexosamine liberated from the cell wall were determined by the anthron method[3] and by the modified method[4] of Elson and Morgan. Fig. 2 shows the experimental results.

From these results, it is concluded that the chitin-like fibre located on the cell wall is not chitin alone, but chitin coated by a melibiose polymer which could be lysed by the lytic enzyme from *Bacillus circulans*.

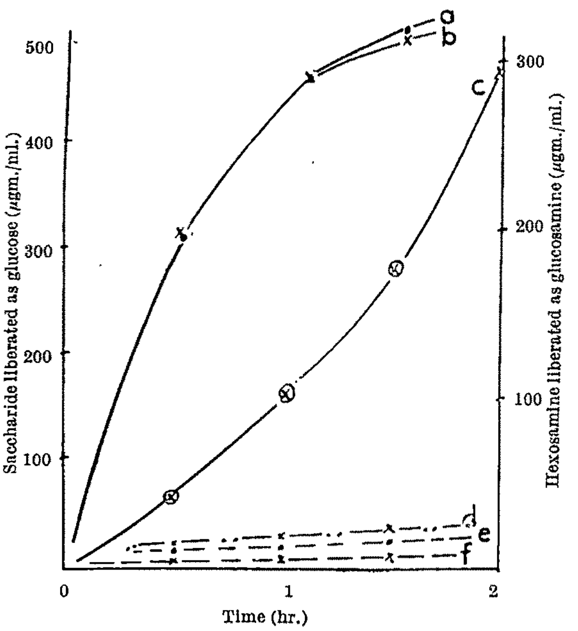

Fig. 2. Lytic action of lytic enzyme and chitinase on the cell wall. 40 mgm. of cell wall was suspended in 20 ml. of enzyme solution (*tris*-buffer *M*/50, *p*H 6·8), and these mixtures were incubated at 37° C. *a*, Saccharide (enzyme: lytic enzyme 24 μgm./ml. as N); *b*, saccharide (enzymes: lytic enzyme 24 μgm./ml. as N + chitinase 20 μgm./ml. as N); *c*, hexosamine (enzymes: same as *b*); *d*, hexosamine (enzyme: lytic enzyme 24 μgm./ml. as N); *e*, saccharide (enzyme: chitinase 20 μgm./ml. as N); *f*, hexosamine (enzyme: same as *e*)

We wish to express our appreciation to Drs. K. Sakaguchi and K. Arima for their valuable suggestions and to Drs. D. M. Reynolds and L. R. Berger who kindly sent us the chitinase.

Factors inhibiting and stimulating Growth of *Mycobacteria* in the Blood and Serum of Non-immunized and Immunized Animals

RESISTANCE to infection with tuberculosis is determined by a number of factors, some of which restrict proliferation of the infective agent in the first stage of the infection. Various authors have demonstrated limitation of growth of the *Mycobacteria* not only in the cells of immunized animals but also in their tissue fluids[1-4].

In our experiments we first verified the results of Kotani *et al.*[5], obtained by culturing *Mycobacterium tuberculosis* (BCG) in drops of blood from healthy and infected rabbits. Like Kotani *et al.*, we found inhibition of growth of the *Mycobacteria* in the blood of the infected animals. On studying the relationship between the amount of inhibition of growth in the blood and serum of infected rabbits and the virulence of the strains or the amount of the infective dose, we found that small doses of a more virulent strain (total dose 0·1 mgm. and 0·4 mgm., intravenously) gave greater inhibition of growth.

We then studied the effect of different sera from normal and immunized rabbits on growth of BCG *Mycobacteria*. The method consisted in culturing BCG cells in a thin layer of 2 per cent glycerin agar on a slide in 2 ml. test serum. The agar was applied to the slide after mixing with a suspension of BCG *Mycobacteria* prepared by the method of Kotani *et al.*[5], in the ratio 10 : 1. After culturing for 48 hr. at 37° C., the slides were transferred to fresh serum and cultured for a further 48 hr. Growth of the *Mycobacteria* was then evaluated by counting the number of cells in each microcolony, as in the experiments of Kotani *et al.*

When BCG *Mycobacteria* were cultivated in the serum of normal rabbits, great differences in their growth activity were observed. In the sera of 24 rabbits examined in the course of one year, the average growth of *Mycobacteria* varied from 2·0 up to 7·5 rods per microcolony in different animals. This decrease of growth in individual sera may be due to a naturally occurring antimicrobial substance[6].

A further increase in the inhibitory action of rabbit sera was observed after immunization of these animals with killed vaccine of *M. tuberculosis* var. *bovis* (Duprey) (Table 1, Fig. 1, *a*, *c*). Heating the sera of non-immunized and immunized rabbits at 56° C. for 30 min. did not affect growth of the BCG cells;

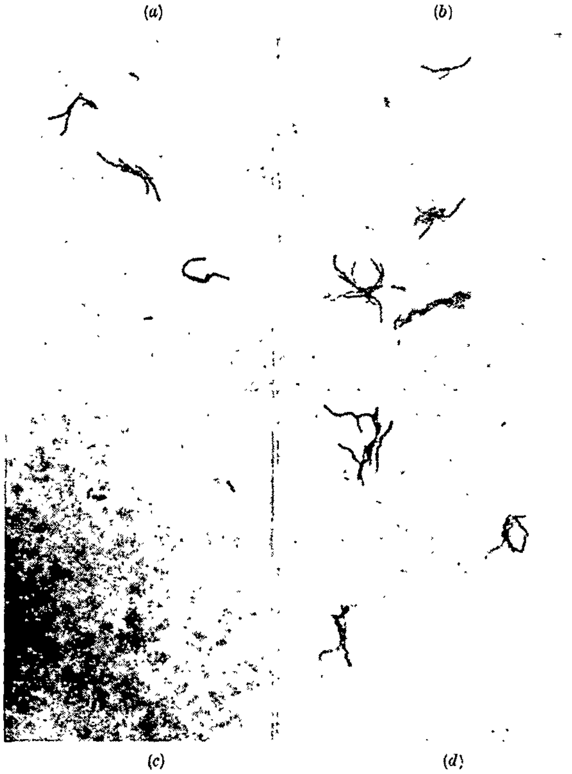

Fig. 1. Growth of cells of *Mycobacterium tuberculosis* var. *bovis* (BCG). (a) In serum of normal, non-immunized rabbits; (b) in the same sera heated to 70° C. for 30 min.; (c) in serum of immunized rabbits; (d) the same serum heated to 70° C. for 30 min. The rabbits were immunized intravenously with 4 mgm. inactivated vaccine (*M. tuberculosis* var. *bovis* (Duprey))

growth increased only when the sera were heated at 70° C. for 30 min. (Table 1, Fig. 1 *b*, *d*). In both groups of animals, growth of the *Mycobacteria* was then the same. It was further found that growth of BCG *Mycobacteria* was completely inhibited by adsorption of the sera of control animals by a concentrated suspension of living or killed cells of these *Mycobacteria*, and that it was not renewed even when the sera were heated at 70° C. This is the basic difference as compared with the serum of immunized rabbits, in which growth of BCG *Mycobacteria* was completely inhibited, but in which, on heating at 70° C., growth of BCG cells reached the same values as in the controls.

Table 1. Growth of Cells of *Mycobacterium tuberculosis* var. *bovis* (BCG) in Serum of Non-immunized and Immunized Rabbits. The Figures refer to the Average Number of Cells in the Microcolony

Rabbit No.	Immunization (mgm.)	Growth of BCG cells in serum			
		Control	Heated at 56° C.	Heated at 70° C.	Adsorbed by BCG
718	—	2·6	2·7	3·8	1·0
721	—	4·4	3·8	6·9	1·0
723	—	4·6	4·2	6·3	1·0
724	—	3·5	3·0	6·5	1·0
725	—	3·0	3·7	8·3	1·0
726	—	3·2	2·9	7·2	1·0
Average		3·5	3·4	6·5	1·0
22	4	1·0	1·0	5·4	1·0
168	4	1·0	1·0	7·2	1·0
170	4	1·0	1·1	3·1	1·0
171	4	1·2	1·1	9·6	1·0
174	4	1·1	1·0	8·7	1·0
Average		1·0	1·0	6·8	1·0

Complete inhibition of growth of *Mycobacteria* was also observed in adsorption of sera by *M. tuberculosis* (Duprey). This did not occur, however, in adsorption of the sera by other groups of micro-organisms (*Saccharomyces cerevisiae, Diplococcus pneumoniae*). We believe the complete inhibition of growth of BCG *Mycobacteria* is due to the disappearance of some growth factor. Indeed, electrophoresis of the sera showed that the alpha-globulin fraction disappeared in serum adsorbed in this way.

These results show that after immunization of rabbits, the level of lysozyme may rise and antibodies may be formed which indirectly affect the inhibitory action of the naturally occurring thermostable antimicrobial substance. The important role of antipolysaccharide antibodies in tuberculosis immunity was described by Seibert[7]. These antibodies combine with the freely circulating tuberculopolysaccharide and thus prevent binding with the effective groups of the natural antimicrobial factor. This factor can then influence the growth of the *Mycobacteria* more effectively. Our results of the study of the relationship between inhibition of growth in rabbit serum and the size of the infection dose showed that the administration of large doses completely suppresses the inhibitory effect of the sera on growth of the *Mycobacteria*. This immunological paralysis is evidence that the inhibitory factor in the serum of immunized animals is of an antibody character.

It was also found that rabbit serum contains a substance promoting growth of *Mycobacteria* which can be removed by its adsorption by *Mycobacteria* suspensions and is to be found in the alpha-globulin fraction of serum. The activating effect of serum albumin[7] may be due to alpha-globulin which is carried over into the albumin in the commonly used fractionation procedures.

Effects of Starvation and Diphenylamine on Carotenoids in *Phycomyces*

In cultures of *Phycomyces blakesleeanus* treated with diphenylamine and methylheptenone, the synthesis of the more saturated polyenes is enhanced at the expense of β-carotene[1,2]. Diphenylamine has a similar effect on cultures of *Rhodospirillum rubrum* at the expense of spirilloxanthin[3]. This effect of diphenylamine has been interpreted as blocking a series of dehydrogenation steps in the transformation of the more saturated to the less saturated carotenoids. Leucine, on the other hand, which stimulates production of β-carotene, contributes to intermediates in carotenoid synthesis.

Two effects are reported in this communication: (1) that of starvation of fully grown mycelial mats of

P. blakesleeanus on the carotenoid content; (2) those of β-ionone, diphenylamine, methylheptenone and leucine on the content and changes in composition when the starved mats are afterwards transferred to an energy-rich medium.

Cultures of *P. blakesleeanus* were grown in 250 ml. Erlenmeyer flasks containing a shallow layer (20 ml.) of medium consisting of 2·5 per cent glucose and 0·3 per cent Difco yeast extract. After 5 days, the medium was decanted off, the mycelium washed three times with sterile water, suspended in sterile water and kept for 24 hr. in the dark. The mycelium was then transferred to 1 per cent Wickerham carbon base medium together with the compound the effect of which was to be tested. The mats were harvested at definite time-intervals and examined for the carotenoids as described earlier[2]. Results are shown in Table 1 for β-carotene and in Table 2 for other components.

Table 1. EFFECT OF STARVATION AND TRANSFER ON β-CAROTENE CONTENT

Treatment	β-Carotene (μgm.)				
	Experiment No. 1	2	3	4	5
Control (5 days growth)	30	33	31·6	32	—
Control (24 hr. starvation)	8·1	10·7	11·0	7	15·7
Control (24 hr. after transfer)	18·6	—	12·0	12	19
β-Ionone (24 hr. after transfer)	156·8	—	—	92	50
Diphenylamine (24 hr. after transfer)	—	—	31·0	—	45
Methylheptenone (24 hr. after transfer)	—	—	9·7	—	—
Leucine (24 hr. after transfer)	—	—	10·7	17	—
Control (no starvation; no transfer; that is, 6 days growth)	43·2	—	—	—	—

Table 2. EFFECT OF STARVATION AND DIPHENYLAMINE ON POLYENE CONTENT

Treatment	Phytoene (μgm.)	Phytofluene (μgm.)	β-Carotene (μgm.)	ζ-Carotene (μgm.)
Control (5 days growth)	33·6	12·3	29·1	3·4
Control (starved 24 hr.)	25·3	3·7	14·1	2·6
Control (1 hr. after transfer)	30·6	5·1	6·2	5·2
Control (4 hr. after transfer)	21·5	5·1	8·5	3·5
Control (12 hr. after transfer)	23·2	5·9	10·9	3·4
Diphenylamine (1 hr. after transfer)	74·0	10·0	24·4	4·3
Diphenylamine (4 hr. after transfer)	48·8	8·1	26·0	5·1
Diphenylamine (12 hr. after transfer)	53·3	7·8	24·3	4·7

It is seen from Tables 1 and 2 that between 50 and 75 per cent of the β-carotene is lost by starvation, and there is limited recovery as a result of transferring the control to the energy-rich medium without further treatment. Furthermore, treatment with methylheptenone, and more surprisingly with leucine, has no effect on β-carotene synthesis. With diphenylamine, however, the β-carotene-level of the pre-starved mat is rapidly restored.

Loss in β-carotene by starvation is not counterbalanced by gains in phytoene, phytofluene or ζ-carotene. (The neurosporene and lycopene contents are too small to be a factor.)

In the presence of diphenylamine the phytoene rises to a higher level than that in the pre-starved control. A net synthesis of phytoene has therefore occurred. This is not true of phytofluene, which although significantly higher than the starved and transferred control is still below the initial pre-starved level.

The effects of starvation and subsequent transfer on carotenoid-levels compared with those of the pre-starved may be summarized as follows:

Control, transferred: net losses in phytoene, phytofluene and β-carotene.

Treated with diphenylamine, transferred: net gain in phytoene, net loss in phytofluene, no change in ζ-carotene.

The restoration of β-carotene to virtually the pre-starvation-level as a result of treatment with diphenylamine requires explanation. Starvation causes no increase in other carotenoids at the expense of β-carotene. If, therefore, diphenylamine is to play its traditional part of anti-oxidant, it must be in preventing further breakdown of polyene precursors. Thus, 1 hr. after transfer, the β-carotene concentration is still decreasing in the control, whereas the trend is completely reversed in the cultures treated with diphenylamine.

Changes in Œstrogen Titre in Stored Urine

NUMEROUS examples of microbiological reactions on steroids have been reported, and it has been suggested that the presence of bacterial enzymes in urine may cause steroid transformations[1].

In preliminary experiments designed to exaggerate any changes which might occur in the œstrone, œstradiol-17β and œstriol values, urine was kept for several weeks, both at room temperature and at 4° C. Significant increases were found to occur in the œstrone and œstradiol-17β fractions of normal male urine but not in the œstriol fraction. Even more striking changes occurred in stored urine from an oophorectomized woman with carcinoma of the breast, collected after the injection of 2·5 mgm. of œstradiol-17β (Table 1).

The results of the chemical determination[2] were confirmed by biological assay (kindly carried out by Mr. P. C. Williams).

Accompanying changes in titre, considerable hydrolysis of the conjugated œstrogens occurs at room temperature. Four urines were analysed for

Table 1. CHANGES IN ŒSTROGEN TITRE IN URINE STORED FOR A LONG PERIOD

No. of duplicate estimations in parentheses. Results calculated as µgm./24 hr.

free œstrogens after ten weeks at room temperature; and from 62 to 74 per cent of the œstrone fraction, 0–45 per cent of the œstradiol-17β fraction, and 62–100 per cent of the œstriol fraction were found to be in the free form.

The increase in the œstrogen content of stored urine could possibly be accounted for by the transformation of one or more of the œstrogen metabolites known to be present in human urine but not measured by Brown's method. After four weeks on the bench or at 4° C. an increase from zero to 12 µgm. of œstriol was found in a specimen to which 16α-hydroxyœstrone had been added, compared with no change in a control urine. Micrococci and diphtheroids were shown to be present in the urine but no attempt was made to determine whether the steroid transformation was due to the presence of these micro-organisms or to the increase in the alkalinity of the urine.

In normal circumstances changes have not been found to occur providing the urine is not kept for more than two days at room temperature or for more than a week at 4° C. (Table 2).

Although there were slight individual variations there is no significant difference between the three sets of results.

If urine is stored for any length of time, hydrolysis of the conjugates and destruction or transformation of the œstrogens may occur. The changes are not predictable or constant and unless analyses are carried out within two days at room temperature, or within one week at 4° C., the results may have little reference to the original titre of œstrone, œstradiol-17β and œstriol. However, it has been shown[3] that no loss of œstrogen occurred in a single specimen of urine stored at −10° C. for two months.

Method for testing the Influence of Drugs and Physical Agents upon Mitosis

JOLLY[1] described how to obtain a convenient number of erythroblastic mitoses in the circulating blood of various species of *Triturus*. The new techniques now made available by phase-contrast microscopy induced us to study these cells with time-lapse photography and micro-cinematography in order to obtain direct evidence of the mechanism of normal and artificially influenced mitosis.

The method can be summarized as follows. According to Jolly the newts are left absolutely without food for 2–6 months; after this period the animals are put in a thermostatic enclosure at 26° C. and fed for some days with earthworms. Generally, between the second and fourth day of feeding a good number of erythroblastic mitoses appear in the circulating blood of the newts. At this moment a blood smear is taken from the tail of the animals and stained as a control. Afterwards the newts are treated according to the aims of each particular experiment (intraperitoneal injections, exposure to radiations or gases, etc.); at various intervals small drops of blood are then taken from the tail of the animals, put on a slide, covered gently with a cover slide and sealed with paraffin.

The preparations are put under the phase-contrast microscope for time-lapse photography or cinematography; in order to keep the temperature constant during observation, the microscope is put in a special thermostatic enclosure. At the same time blood smears are prepared and stained. In certain cases it may be also advisable to act directly on the surviving erythroblasts of an untreated newt, adding the substance to the blood drop or exposing it to radiations, gases, etc.

Thus it is possible to follow and to document with films or photographs the course of mitosis and the various alterations eventually induced. Additional results are obtained from the stained smears.

Obviously, a great number of modifications to the method we have outlined may be necessary. In fact, our test is adaptable to many different experimental conditions, but is particularly suited when clear morphological evidence is needed. A series of detailed papers is in preparation, dealing with normal mitosis and the influence of various substances and physical agents upon it.

Splitting of the Electrophoretic Pattern of Serum Albumin during Short-term Action of Pepsin at Room Temperature

THE heterogeneity of serum albumins consisting of several molecular sub-units has been established by chemical as well as by electrophoretic assays. However, while chemical fractionation of serum albumins led to well-identified products, electrophoretic procedures did not show equally consistent results. In this latter case, the separation of the sub-units was found to vary with *p*H, ionic strength, length of run, and other factors not well understood[1]. It could be shown, moreover, that the splitting of albumin into a number of boundaries is a reversible process and does not represent denaturation on artefacts.

A similar but apparently irreversible splitting of serum albumin into molecular sub-units, by the short-term action of pepsin, is demonstrated in the present electrophoretic studies carried out by Tiselius's moving boundary method.

The analyses were initiated with crystalline bovine serum albumin (Armour). 100 mgm. albumin was dissolved in approximately 10 ml. distilled water

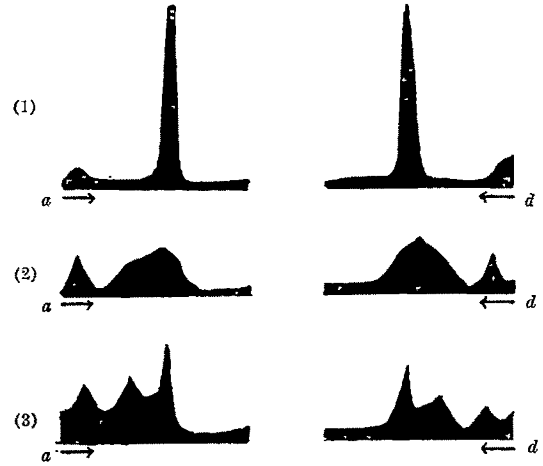

Fig. 1. Electrophoretic pattern of 1 per cent crystalline bovine serum albumin incubated with pepsin in a ratio 1 : 100 at room temperature: (1) at *p*H 7·0 for a 6-min. period; (2) and (3) at *p*H 3·0 for a 2- and 6-min. period respectively at room temperature

and the *p*H adjusted to 3·0. The solution was then incubated with 1 mgm. crystalline pepsin (Nutritional Biochemicals Corp.) at room temperature for 1–6 min., after which a proportional mixture of crystalline veronal and sodium veronal was dissolved in the sample in order to inactivate the ferment and to make its barbiturate – barbituric acid concentration equal to that of the buffer solution used in the electrophoretic experiment.

For the preparation of albumin from fresh cow, horse, rabbit and cock serum, a simple and relatively quick method had to be utilized that would be applicable to small amounts of blood, and which would provide an electrophoretically homogeneous product. The trichloracetic acid–acetone extraction procedure of Kallee and associates[2], modified slightly, gave satisfactory preparations. In most cases 3 ml. of the respective serum sample was used for the extraction. The acetone of the extract was removed by vacuum distillation at room temperature and the remaining aqueous suspension of albumin redissolved at *p*H 6·5 by addition of sodium hydroxide. The solution was clarified by high-speed centrifugation, dialysed against 4 l. of distilled water in the cold for 24 hr., after which the *p*H was brought to 3·0 and incubated with pepsin in a 1 : 100 ratio as described above. The protein content of the samples was determined according to the method of Gornall *et al.*[3]. The readily reproducible electrophoretic assays were made in 2 ml. cells by means of a Perkin–Elmer electrophoretic apparatus, model 38, using veronal buffer of *p*H 8·6, ionic strength 0·1, and a potential gradient of 7·10 to 7·30 V./cm.

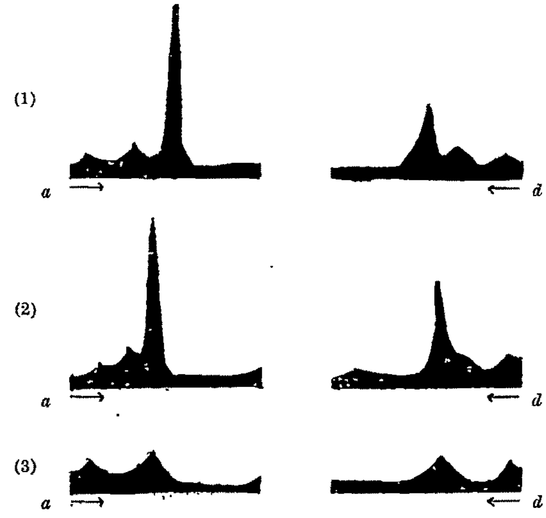

Fig. 2. Electrophoretic patterns of solution of (1) 0·87 per cent rabbit serum albumin, (2) 0·91 per cent cock serum albumin, and (3) 0·64 per cent horse serum albumin incubated with pepsin in a ratio 1 : 100 for a 6-min. period at room temperature

Fig. 1 shows the elctrophoretic pattern of 1 per cent crystalline bovine serum albumin after incubation with pepsin for 2 and 4 min., respectively. The two patterns differ primarily in the number and shape of their boundaries, which would indicate that the separation of the boundaries into two or three peaks depends upon the time-period allotted to the pepsin albumin constituents to react with each other.

Fig. 2 shows the electrophoretic pattern of rabbit, cock and horse serum albumin as influenced by the action of pepsin. On comparing the patterns of Figs. 1 and 2 the differences between the species different albumin samples are easily recognizable.

Thanks are due to Mr. J. A. G. Larose for valuable technical assistance.

Has Water a Specific Taste?

In 1949 it was found that water applied to the tongue of the frog elicited an electrical response from the glossopharyngeal nerve[1]. This response was produced by specific fibres[2]. It was first thought that these 'water' fibres might serve a particular purpose in water regulation in amphibians living in fresh water. These findings also revived the old problem of whether warm-blooded animals and man possess similar specific taste fibres mediating what we might call a water taste. The late Prof. David Katz of Stockholm, who believed this to be the case, often asked in his examinations: What is the taste of water? The correct answer was 'wet'.

Such a belief was strengthened by the fact that Liljestrand[3] demonstrated that as weak a salt solution as 0·009 *M* sodium chloride which does not taste salty could be distinguished from distilled water with 100 per cent certainty if the solutions had been boiled and cooled down again to the same temperature.

Experiments on cats, dogs, pigs[3,4] and recently even monkeys have shown that these animals possess specific nerve fibres in their chorda tympani which respond to the application of water to the tongue. In the rat, on the other hand, an application of water to the tongue does not produce any positive response as it does in the cat; but a negative response is obtained which is due to an abolition of the rather high spontaneous activity of the salt fibres[5].

In the animals which possess specific water fibres as well as salt fibres, the discrimination of weak salt solutions from pure water could thus be elaborated by a dual system of salt and water fibres, the activities

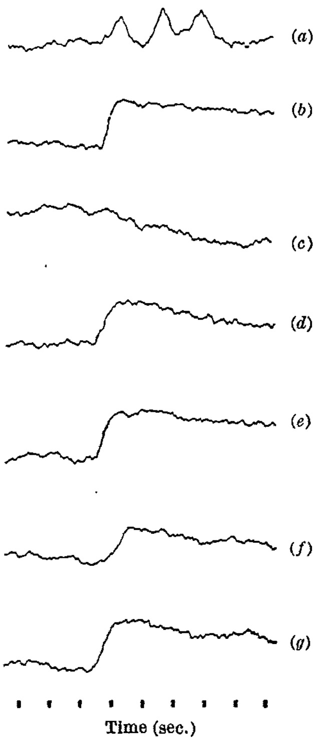

Fig. 1. Integrated responses of the whole chorda tympani nerve of man to touch and to various solutions flowing over the tongue: (a) touch, (b) 0·5 *M* sodium chloride, (c) distilled water, (d) 15 per cent sucrose, (e) 0·04 per cent saccharine, (f) 0·02 *M* quinine, (g) 0·2 *M* acetic acid

of which contrast with each other because of their reciprocal mode of stimulation, in the same way as do the cold and warm fibres in our thermal discrimination. A few years ago preliminary experiments on man were performed by Dr. C. Åhlander and one of us (Y. Z.) on man during operations on the middle-ear[6]. Out of ten trials very weak responses were obtained in two cases to touch, cold and gustatory stimulation of the tongue. The responses were, however, only very faintly audible in the loud-speaker and could not be recorded.

In recent attempts, made in the otological clinic of Karolinska Sjukhuset, we have been able to record the electrical response from the chorda tympani during operations carried out to mobilize the stapes in the middle-ear. In two out of six cases we have been able to record the integrated electrical response of the nerve when the tongue was stimulated by touch and various solutions. As will be seen in Fig. 1 there is a good response to 0·5 *M* sodium chloride solution as well as to 15 per cent sucrose, 0·04 per cent saccharine, 0·02 *M* quinine hydrochloride and 0·2 *M* acetic acid.

The application of water to the tongue, however, is followed by a negative response, in that water abolishes the spontaneous activity of the taste fibres just as has been described in the rat. As our evidence, however, is based upon successful experiments in only two humans, we have to collect more evidence before being able to say definitely that man lacks a specific water taste. Introspectively, however, it seems to us most likely that water does not elicit any positive taste sensation. The action must be of negative character in that water abolishes or decreases the resting activity of taste fibres, particularly that of salt fibres. The specific effect of water on taste in man can thus be looked upon as being of the same nature as that of blackness upon vision. This is in interesting contrast to the monkey, in which we have recently found a comparatively strong positive response to water.

Haptoglobin Types in American Negroes

Since the discovery by Smithies[1] that there are genetically controlled serum haptoglobin types, two reports on the distribution of these types among African Negroes have been published. Sutton *et al.*[2] noted a 49 per cent incidence of haptoglobin type 1-1 among Liberian and Ivory Coast natives. A similar percentage (54 per cent) was found by Allison *et al.*[3] in Nigerians. However, a great discrepancy between the two studies was described by Allison, who found that 32 per cent of the Nigerian sera did not contain demonstrable haptoglobins—a condition not reported by Sutton. Allison pointed out that since the Michigan investigators did not add hæmoglobin to the sera prior to electrophoresis, and the starch gel was not stained with benzidine, sera devoid of haptoglobins could be readily confused with those of type 1-1.

Nosslin and Nyman[4] have shown that, in the presence of hæmolytic anæmia, the amount of serum haptoglobin may be greatly decreased or absent. That the high incidence of malaria and hæmoglobinopathies associated with red cell destruction in African Negroes might obscure the true incidence of their haptoglobins was implied by Allison. Nevertheless, he felt that the phenomenon of 'ahaptoglobinæmia' should be ascribed to a genetic mechanism.

Since malaria is extremely rare in the north-western part of the United States, the Seattle area seemed especially suitable for testing the serum of American Negroes for their haptoglobin types. Employing Smithies's method[5], starch gel electrophoresis was performed on the serum of 406 random Negro donors at the King County Central Blood Bank. Oxyhæmoglobin was added to a concentration of about 300 mgm. per cent prior to electrophoresis. The resultant starch strips were treated with benzidine and the haptoglobin type read immediately. Amido black *B*-10 staining was then carried out. With this method, the benzidine-stained bands were characterized by a permanent black colour distinct from the blue non-hæmoglobin protein.

A control group of 100 sera from white donors showed a distribution of haptoglobin types very similar to that reported by other authors[2,3,6]. However, the Negro sera, as indicated in Table 1, were different in several respects from those described in Africans.

Complete absence of haptoglobin was observed in a much smaller percentage of subjects than reported

Table 1. HAPTOGLOBIN TYPES IN NEGROES

Locale	Number tested	Haptoglobin types (per cent)				
		1-1	2-2	2-1	2-1 (mod.)	Absent
Nigeria (ref. 3)	99	53·5	3·0	11·1	—	32·3
Liberia and Ivory Coast (ref. 2)	142	48·7	9·1	42·3	—	—
Seattle	406	26·4	21·4	38·2	9·8	4·2

in Nigerians. Recognition of such individuals was difficult because of the necessity to distinguish their sera from that containing very small amounts of hæmoglobin-binding protein. In about 5 per cent of cases, the area stained with benzidine was so faint that it was necessary to repeat the electrophoresis to confirm the presence of haptoglobin. In several instances, new samples were obtained; but the same phenomenon was observed.

Seventeen, or 4·2 per cent of all sera tested, appeared to be completely devoid of haptoglobin. The donors of these samples were not anæmic and none had a history of malaria. Of six red cell specimens from 'ahaptoglobinæmic' Negroes neither unusual hæmoglobins nor a deficiency in glucose-6-phosphate dehydrogenase, which is associated with hæmolysis due to a variety of agents[7], could be demonstrated (hæmolysis performed by Dr. A. G. Motulsky, University of Washington School of Medicine). Inheritance studies of 'ahaptoglobinæmia' have so far been inconclusive. However, in some families, both parents of a subject with 'ahaptoglobinæmia' appear to carry a pair of normal haptoglobin genes. Thus, it is clear that if a genetic mechanism is involved, the responsible gene cannot be an allele at the *Hp* locus, nor can it be a Mendelian dominant.

Forty of the sera (9·8 per cent) showed a pattern similar to that of type 2-1, but distinctly different in having a much heavier concentration of haptohæmoglobin in the region just behind the beta-globulin (as seen in type 1-1) as well as the fastest of the zones in the 'alpha-beta' region. The other bands characteristic of type 2-1 were either entirely absent or scarcely discernible. In a recent paper, Connell and Smithies[8] describe the same unusual type, and illustrate the starch gel patterns of purified haptoglobins of this and the three common types. They suggest the tentative name '*Hp* 2-1 (mod.)' for this modified type. It is not yet known whether the pattern is due to a third allele at the *Hp* locus or to the effect of a modifying gene. Studies of its inheritance are in progress.

The lower incidence of 'ahaptoglobinæmia' and higher incidence of the Hp^2 gene in Seattle Negroes as compared with African natives may be explained by the following factors: (1) The present study was performed on the serum of healthy blood donors from an area essentially free of malaria. (2) Seattle Negroes represent several sections of Africa, where haptoglobin type distribution is probably variable. (3) Racial intermarriage in America, known to have produced an admixture of 30 per cent of European blood group genes in Negroes[9], undoubtedly has a similar influence on haptoglobin gene frequencies.

Hæmoglobin *N* in Portuguese Guinea

IN 1956 a survey of hæmoglobin types in Liberians by Robinson, Zuelzer, Neel, Livingstone and Miller led to the discovery of two 'fast-moving' hæmoglobins which were provisionally designated Liberian I and II, the first abnormal complement moving on electrophoresis at *p*H 8·6 faster than the second and both moving faster than normal adult hæmoglobin *A*. Liberian I was at first supposed to be identical with hæmoglobin *J* discovered by Thorup, Itano, Wheby and Leavell[1]; but further study by Ager and Lehmann[2] demonstrated a difference in the behaviour of these hæmoglobins, Liberian I migrating faster than *J* at alkaline *p*H, though slower than *H* or *I*. At acid *p*H Liberian I separates from *A* towards the anode while *J* does not. Liberian I, thus being a new hæmoglobin, was called hæmoglobin *N*.

Hæmoglobin *N* is a rare type, having been found only eight times in the survey by Robinson *et al.*[3] among the Mande tribe in Central Liberia. During a survey of abnormal hæmoglobins in Portuguese Guinea we have found fourteen Africans with this rare variant. We are indebted to Dr. H. Lehmann, of the Department of Pathology, St. Bartholomew's Hospital, London, for having classified the abnormal hæmoglobin in the first instance when it was found. Fig. 1 shows its mobility on paper electrophoresis at *p*H 8·6 in the hands of this investigator. Subsequent hæmoglobins have been classified by ourselves in comparison with samples of hæmoglobins *J* and *H* very kindly supplied by Dr. Lehmann, the original hæmoglobin *N* found by us, and a sample of hæmoglobin *K* obtained at a previous survey in the St. Thomas and Prince Islands[4].

Hæmoglobin *N* was found in Portuguese Guinea in the following tribes in random samples of blood

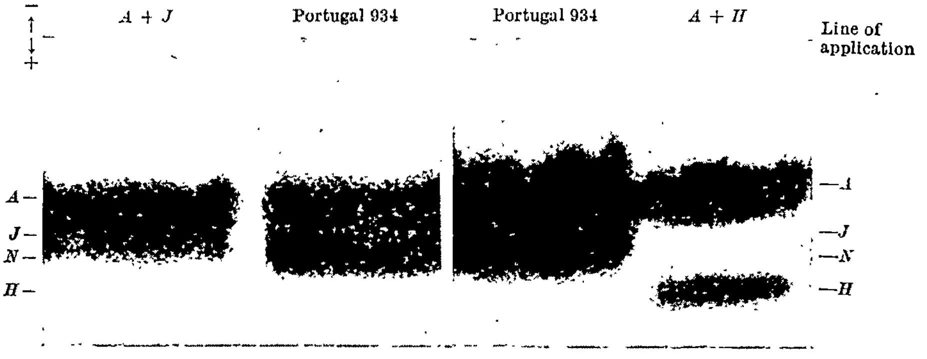

Fig. 1. Comparison of Portugal 934 with hæmoglobins $A+H$ and $A+J$. It will be seen that at paper electrophoresis *p*H 8·6 the 'fast-moving' component of Portugal 934 is slower than *H* and faster than *J*

(number of samples given in parenthesis): Fula, 4 cases (1,553); Beafada, 1 (797); Pajadinca, 2 (300); Sôsso, 2 (94); Balanta, 1 (776); Mancanha, 1 (534); Manjaco, 3 (758).

The first four tribes are Moslems, the latter Fetichists. The general search allowed the examination of 9,224 samples of blood gathered throughout the Province.

Oxygen Consumption of Different Forms of Stable L *Proteus* P 18 growing in Hypertonic Liquid Medium

IN previous work we have studied the oxygen and glucose consumption as well as the lactic acid production of the *Proteus* Ahmed bacillus and of a stable L form which is derived from it[1].

We then noticed that the oxygen and glucose consumption of the bacillus were respectively 4·0 and 5·1 times higher than that of the L form, whereas the lactic acid production was only 2·4 times greater. The share of anaerobic glycolysis in the glucose degradation was more considerable with the L forms than in the rod forms.

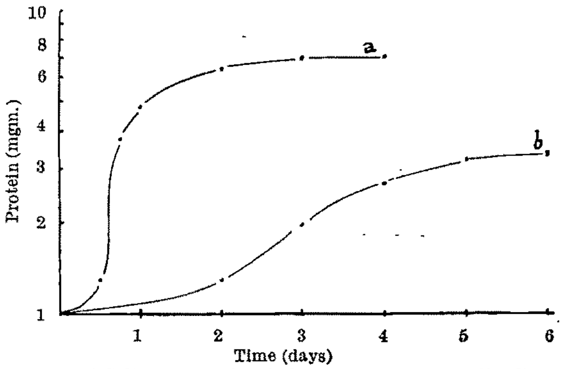

Fig. 1. (*a*) Culture suspensions in hypertonic medium; (*b*) culture films (*voiles*) according to Tulasne (ref. 2)

Owing to the heterogeneity of the L form cultures, it was interesting to investigate the metabolic characteristics of several morphological forms: large, small and elementary filterable bodies. First, a technique for obtaining readily large quantities of L forms was devised, because the usual methods[2,3] were found to be laborious and difficult. We have used films (*voiles*[2]) of L forms of *Proteus* P 18 to produce culture-suspensions in hypertonic medium. Our culture medium was composed of broth containing 20 per cent horse serum, 2,000 penicillin units per ml. and saccharose added to make up a final concentration of 0·3 *M*. Just after seeding, the

FRACTIONING METHOD FOR L FORMS IN HYPERTONIC MEDIUM

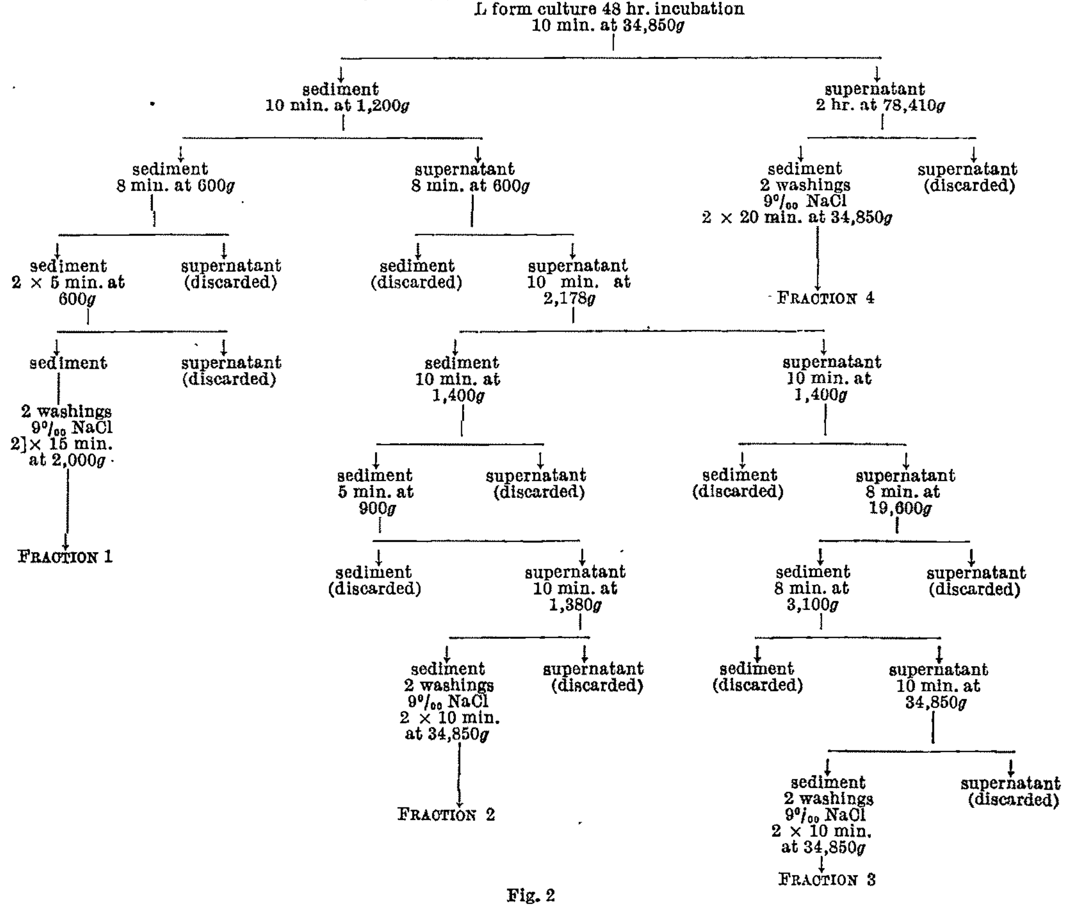

Fig. 2

culture was submitted to vigorous shaking for 30 min., after which it was maintained for 24 hr. at 37° C. Such cultures can easily be transplanted continuously in liquid hypertonic subculture as a normal bacterial suspension. Fig. 1 shows the increase of dry substance plotted against time for one of our cultures suspended in a hypertonic medium, and for a Tulasne culture (films)[2]. The phase of rapid growth in our culture occurs between 18 and 48 hr., whereas in the film cultures the growth takes much longer and reaches its maximum on the fifth day. As regards the morphological aspect, our cultures in hypertonic liquid medium contained large, swollen bodies, 8–12μ in size, as well as small and elementary bodies described by many authors. We have not been able to ascertain the presence of large bodies (20μ) which existed in the original cultures.

The different morphological forms of our cultures were separated by differential centrifugation followed by washings with 0·3 *M* saccharose solution (except where washing with 9 per mille sodium chloride is specified—Fig. 2). The respiration of the different fractions was studied in a Krebs medium with a Warburg apparatus, and the values have been referred to deoxyribonucleic acid (Fig. 3).

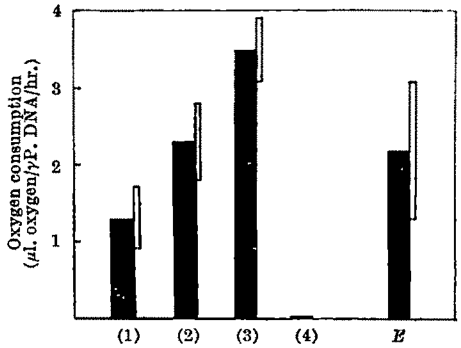

Fig. 3. Oxygen consumption of the various fractions of L forms. Values for large bodies (1), medium bodies (2), small bodies (3), elementary bodies (4) and total culture (*E*)

The results lead us to think that the small bodies of fraction 3, the metabolism of which seems to be most intense, correspond to a state of active proliferation. It appeared also that the oxygen consumption referred to deoxyribonucleic acid was practically nil for fraction 4 (elementary body). It seems to have lost its enzymatic apparatus for the aerobic degradation of glucose.

Supposing that the L forms are representative of a transition from one state to another—that of viruses—the elementary bodies would form a preliminary stage characterized by an already considerable reduction of the enzymatic apparatus of these micro-organisms.

BIOLOGY

Changes in Lymphocytes during Antibody Production

During the course of an investigation[1] into the function and life-cycle of lymphocytes, a number of physical techniques were employed to determine the identity of cells isolated from various sources, for example, lymph glands, thoracic duct, thymus, spleen, blood, etc. The average cytoplasmic refractive index of small lymphocytes obtained from the above sites had been determined with a fair degree of certainty. It was noted that in chronically infected rats (rat pneumonia) the small lymphocytes, whatever their source, showed a significantly raised cytoplasmic refractive index. The subcutaneous injection of a particulate antigen (T.A.B.) produced a similar rise preceding but paralleling the rise in the antibody titre of the serum and thoracic duct lymph. We suggest that the refractive index change in the cytoplasm of the small lymphocyte is due to increased protein concentration connected with the mechanism of production of antibodies. A detailed study of this phenomenon is in progress.

Zone Electrophoresis of Rous Sarcoma Virus

The value of zone electrophoresis in the study of animal viruses has been demonstrated by previous workers[1,2]. By this method new criteria for the classification of animal viruses can be obtained. In addition, the study of electrophoretic inhomogeneity of viruses is of special interest. Thus it could be shown for polivirus type I that the virus activity is shared by at least two components with different electrophoretic mobilities[3].

Zone electrophoresis might also be of value for the purification of viruses. In this report, preliminary results of electrophoresis of a cancer virus are given.

The supernatant of Rous sarcoma tissue cultures was chosen as a source of virus. Chicken tissue cultures were infected with Rous sarcoma virus and passaged serially by trypsinization for about two months until almost all cells showed the characteristics of Rous sarcoma cells and the titre of Rous virus in the supernatant was at least 5 log plaque-forming units per ml. The supernatants were then collected and treated by two cycles of centrifugation, one for 10 min. at 5,500*g* and a second for 60 min. at 54,000*g*. In some experiments, hyaluronidase in a final concentration of 7 units/ml. and trypsin in a final concentration of 0·025 per cent were allowed to act on the supernatant for 20 min. at 37° C. before centrifugation. The final pellet was taken up in 0·3 ml. veronal buffer *p*H 8·2 and mixed with an equal amount of 25 per cent cane sugar solution in buffer before introduction into the electrophoresis column. A detailed description of the electrophoresis apparatus and of the electrophoresis technique is given in previous papers[1,2]. Veronal buffer of *p*H 8·2 containing 47·6 gm. sodium diethylbarbiturate and 11·5 ml. *N*/6 hydrochloric acid in 4·3 l. of distilled water was used. Electrophoresis was allowed to proceed at room temperature for 3 hr., with a voltage gradient of 3·5 V./cm. and a current of 20 amp.

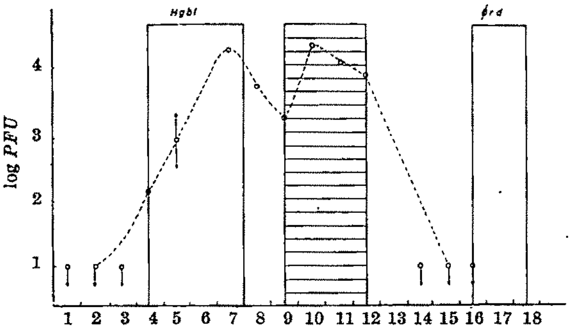

Fig. 1. Zone electrophoresis diagram showing the distribution of Rous sarcoma virus activity in log plaque-forming units (*PFU*) for each consecutive electrophoretic fraction of 0·8 ml. each, indicated on the abscissa. The position of the reference substances are indicated by the first and third vertical column and the opalescent zone containing the impurities by the second vertical column

In the first experiments, rabbit hæmoglobin and phenol red were added as reference substances. In some experiments, decomplemented and defatted[1] horse serum to a final concentration of 0·2 per cent was added to the sugar gradient to stabilize virus activity. The content of electrophoresis column was run out by taking samples of 0·8 ml. each. The virus activity of each fraction was assayed on the chorio-allantoic membrane of the chick embryo by the pock-count method, using 10 eggs per fraction[3].

The migration of the white opalescent initial zone containing a great deal of impurities as judged by electron microscopic analysis[4] could easily be followed against a dark background during electrophoresis. After an electrophoresis of 3 hr., this slightly broadened zone was apparently still compact, the lower part being still white opalescent with a sharp inferior border, whereas the upper part appeared slightly bluish. As can be seen from Figs. 1 and 2, this zone assumes a position intermediate between that of the rabbit hæmoglobin and phenol red under the conditions of the experiment at *p*H 8·2. From the same diagrams, it can be seen that a first peak, representing about 30–50 per cent of the virus activity, separated completely from the principal opalescent zone and migrated slightly faster than rabbit hæmoglobin at *p*H 8·2. As the same finding has been made in similar experiments in which no hæmoglobin was used as reference substance, it must be concluded that the mobility of the first peak of virus activity is independent of the presence of hæmoglobin.

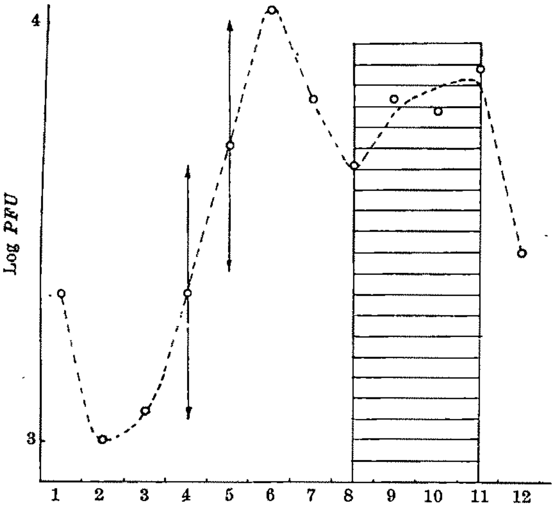

Fig. 2. Zone electrophoresis diagram of Rous sarcoma virus without reference substances. The vertical column represents the opalescent zone. The vertical arrows represent the confidence intervals. *PFU*, plaque-forming units

A second peak of virus activity was confined to the opalescent zone. Only by a further development of the electrophoresis at a low temperature and over a period of more than 3 hr., can it be established whether the virus activity found in this zone can be further separated from the bulk of impurities.

A third, minor peak of virus activity, with a higher mobility than the principal opalescent zone, was found only in some experiments, not discussed in this communication, and will be the subject of further analysis.

Experiments are now under way to establish the significance of the findings in relation to the possible electrophoretic inhomogeneity of Rous sarcoma virus as well as to its purification.

Persistence of Sudanophilic Lipid in Sections of Mummified Tissue

PARAFFIN sections of Egyptian mummy tissues made by various workers[1–4] have shown the appearances of adipose tissue; examinations of mummy tissues by frozen section have been infrequent[3,5]. Shaw[3] failed to detect fat globules in frozen sections of adipose tissue from eighteenth-dynasty canopic material, namely, mesentery and gall-bladder serosa. Lipids have been demonstrated by chemical methods in mummy tissue[6,7] and proved to consist largely of fatty acids with traces of unaltered fat. These fatty acids have been thought to be derived not only from neutral fat but also from protein during the embalming process. Fatty acids and cholesterol have also been demonstrated by chemical methods in remnants of mummy brain[8].

While preparing an Egyptian mummy head for histological examination, it was noted that whitish-yellow material had persisted in the subcutaneous tissues, especially of the scalp, and in the marrow spaces of the calvarium. Frozen-sections of the scalp of the occipital region showed sudanophilia of the subcutaneous and subaponeurotic tissue with a light orange-red colour to a mixture of sudan III and IV and an intense black colour to sudan black. The material was obviously crystalline and proved largely to be plainly birefringent in bundles of thin acicular crystals on examination with polarized light. No red coloration was obtained with nile blue sulphate, and Von Kossa's stain for calcium showed moderate blackening confined strictly to the lipid areas. Sudanophilia and birefringence were reduced after treatment with ethyl alcohol, acetone and more markedly with chloroform and ether. Sudanophilic material which was not anisotropic was noted in small quantities in the remains of sebaceous glands and in small cutaneous nerves, presumably derived from myelin breakdown.

It is known that neutral fats and fatty acids, although mono-refringent in the fresh states, become crystalline on cooling or after fixation in formalin. This phenomenon is frequently seen on storage of animal tissues in formalin and is sometimes very obvious in old museum specimens.

Hunt[9] has described the appearances of the subcutaneous fat in female human bodies remaining in cool, dry surroundings with some air movement in which they would have eventually become naturally mummified. In one body, dead for 50–70 days, the subcutaneous fat spaces contained much granular material which did not dissolve in the usual fat solvents and stained only slightly with sudan black. In the superficial fat were collections of narrow pointed crystal spaces, thought to represent fatty acids. In a further body, dead for about 100 days, fat cells were mostly broken up and replaced by granular material and scanty crystal spaces.

The better preservation of lipid, its crystalline nature and association with calcium in the mummified scalp tissue suggests that some process other than simple dehydration had played a part. It may be that the alkalis used in mummification in Egypt produced some degree of hydrolysis of the neutral fats to fatty acids associated with calcium in the subcutaneous tissues.

My thanks are due to Mr. D. McSeveney for technical assistance.

In vitro Cultivation of the Histotrophic Stages of *Haemonchus contortus* and *Ostertagia* spp.

LAPAGE[1] working with *Haemonchus contortus* reported in 1933 that: "Attempts have been made to cultivate the parasitic larval stages, a method having been found by which the free-living infective third stages may be exsheathed and sterilized, so that the first parasitic stages may be obtained and studied further in sterile media of known composition. Although these first parasitic stages have been studied in hanging drops in more than 200 media designed to imitate environmental factors to which parasites are presumably exposed in the body of the host no success has been obtained".

Stoll[2] found that exsheathed sterile *H. contortus* infective larvæ underwent the first parasitic ecdysis when maintained in various balanced salt solutions. Apart from the formation of a buccal cavity, no growth or differentiation occurred and the larvæ died soon after ecdysis occurred.

Weinstein and Jones[3] were the first to culture successfully *in vitro* the histotrophic stages of a parasitic worm, and in fact produced sexually mature adults of *Nippostrongylus muris*. Attempts by these workers to culture the parasitic stages of *Strongyloides* spp. were not successful, even in media in which *N. muris* had developed to adults[4].

In this department early attempts failed to culture *H. contortus* and *Ostertagia* spp. parasitic stages in the medium described by Weinstein and Jones. As a result, a programme was undertaken systematically to test, separately and in combination, the various nutrients which previous workers had found to support *in vitro* growth of nematodes. The components included chick embryo extracts, Hela cell cultures, various liver extracts, sodium caseinate, casein hydrolysates, serum, Tyrode solutions and various balanced salt solutions used in tissue culture methods. Various static and roller tube culture methods were tested, most media being set up under both conditions. The effect of transfering media on successive days was also investigated.

Success was eventually obtained with a medium, now in regular use, consisting of chick embryo extract, autoclaved sheep liver extract, casein hydrolysate and sheep serum in a 2 : 2 : 2 : 1 ratio. This is remarkably similar to the medium recommended by Weinstein and Jones, but differs in the mode of preparation of the liver extract. In this medium, using a roller tube technique, growth and metamorphosis of larval stages occurs up to the adult stage in about 24–30 days. By this time, however, the individuals have become recognizably stunted. The media require changing every 72 hr. for the first 12 days.

Re-investigation of the cause of the early failure suggests that the original fresh liver extract contained a lethal factor, and it appears that the nutrient factors in fresh liver are subject to considerable variation. The method of liver preparation now in use is that described by Nicholas[5], with the difference that only a single sterilization by autoclave is made.

Effect of Gibberellic Acid on Length and Number of Epidermal Cells in Petioles of Strawberry

INCREASE in height is perhaps the most widely observed effect of gibberellic acid on plants. This is mainly due to longer internodes, and not to a larger number of nodes. The increased length of an internode has been variously ascribed to increases in numbers of cells, increases in length of cells and to both. Stowe and Yamaki[1], reviewing earlier (especially Japanese) work, conclude that "cell elongation in most cases seems to predominate as the result of gibberellin application". Since then Greulach and Haesloop[2] could find no significant increase in size of cell when the lengths of internodes of *Phaseolus vulgaris* were increased by a mean of 2·28-fold by the application of gibberellic acid. They concluded that cell division had been promoted. Further information is clearly desirable. In the strawberry plant, height is determined mainly by the length of the leaf petioles. The results presented in this communication show that increases in length of petiole brought about by the application of gibberellic acid involve increases both in the number and the length of cells in the epidermis.

Plants of the variety Redgauntlet were grown in pots in two growth cabinets at 60° F. in a 12-hr. photoperiod. The cabinets were illuminated at two different intensities (about 800 and about 1,200 foot candles) with equal numbers of 'Warm White' and

Table 1

Treatments and treatment differences	Length of petiole (mm.)	Mean length of cell (μ)	Calculated No. of cells

G.A., gibberellic acid.

'Northlight' fluorescent lamps supplemented with tungsten filament lamps. Following an initial application of 16 μgm. per plant on June 18, gibberellic acid was applied in aqueous solution at the rate of 8 μgm. per plant twice weekly until August 12. The solution was applied in single drops of 0·1 ml. which were immediately covered with cover slips. The drops were absorbed in about 24 hr. It is possible that some loss of activity occurred during this period. This level of treatment gave the moderate increases in length of petiole thought to be desirable for this investigation and avoided gross morphological changes such as can be obtained with larger doses. There were five treated and five untreated plants in each growth cabinet.

On August 14 the petioles were measured from the point of insertion of the stipulary leaf bases to the conjunction of the laminæ. The second leaf to emerge on each plant after the commencement of treatment was selected for cell measurement. Leaves in this position on the stem were fully extended and also showed a substantial effect of treatment. The petioles were preserved in 50 per cent alcohol. For cell counts the petioles were removed from the alcohol and soaked in water over-night. Narrow strips of epidermis were peeled away from nine separate, equally spaced locations on each petiole. After clearing in lactic acid the strips were mounted in glycerine and inspected under the microscope. The image was projected on to a ground-glass screen for cell measurement. The cells were measured in tandem pairs, five pairs being measured at random in six different fields for each of the nine locations, making a total of 540 cells measured on each petiole. Guard-cell areas were deliberately avoided. Mean length of cell was obtained for each petiole, and this, divided into the length of petiole, gave a figure for 'number of cells' for each petiole.

Lengths of petioles, mean lengths of cells and the calculated figures for 'number of cells' were statistically analysed and the standard errors are tabulated together with the results. Percentage increases were calculated separately for length of petiole and the two component factors.

Significant differences between treated and untreated plants were obtained at the higher light intensity. At the lower intensity the differences were about half those at the higher, and were not significant. The overall effect of gibberellic acid at the two light intensities was a significant increase in length of petiole, composed of a significant increase in both mean length of cell and mean calculated number of cells. The percentage figures suggest that the increase in length of petiole was contributed to more or less equally by increases in both components.

The lesser effect of gibberellic acid at the lower light intensity is noted; but, as this work forms part of a broader investigation into the effect of a number of environmental factors on length of cell and number as components of length of petiole, a discussion of this and of the effect of light intensity is held over for another occasion.

We wish to thank Dr. M. R. Sampford for advice on the statistical treatment of the data, Mr. J. Stewart and Miss Kamala Saggar for measuring the cells, and Plant Protection, Ltd., for supplying the gibberellic acid.

Effect of Residual House Spraying in the Plains on Anopheline Densities in Huts on the Pare Mountains

AN experiment is in progress in the Pare area of Tanganyika to find whether or not malaria can be controlled by residual treatment of huts with dieldrin. The area is 3–4,000 square miles, involving a population of 100,000. The Pare Mountains extend along the length of the treated area, at an altitude of about 4,000 ft. above sea-level. The population is about equally divided between the malarious plains and the mountains, which are separated by a steep escarpment. Surveys of the human population did not suggest that active transmission occurred on the mountains[1]. Huts were treated only in the plains, and the first cycle of spraying was completed in November 1955. Subsequent treatments continue at intervals of 8 months.

The majority of the mountain population live at about 2,000 ft. above the plains; but villages occur on the sides of the mountain in a few areas where the escarpment is less steep. Spray catches were made in four villages above the escarpment, and in one village half way up it. Spray catches were also made at the foot of the mountain, in the area that was eventually treated with dieldrin. The results are shown in Table 1.

Above the escarpment, before residual spraying, there were very low densities of *A. gambiae* in huts and *A. funestus* compared with those at the foot of the mountain, but half-way up there was a substantial infestation of huts by *A. funestus* in May. After residual spraying, *A. funestus* disappeared from huts on the mountains as well as in the plains, and densities in huts of *A. gambiae* were also reduced.

These findings suggest that the presence of *A. gambiae* and *A. funestus* in huts on the mountains is dependent on direct infestation from the plains, followed to some extent also by seasonal reinfestation of breeding places, as *A. gambiae* was found breeding in a rice field on the mountains before residual spraying was carried out. Garnham[2] has discussed the factors that give rise to malaria transmission at high altitudes, and has shown how malaria, largely absent in the highlands of Kenya before the First

Table 1. Densities of *A. gambiae* and *A. funestus* in Huts at Different Levels in the Pare District

	Before dieldrin					After dieldrin									
	1955					1956					1957				
	Jan.	April	May	July	Oct.	Jan.	April	May	July	Oct.	Jan.	April	May	July	Oct.
Untreated huts 2,000 ft. above valley (20–24 huts)

A. funestus	2	24	75	28	2	0·1	0	0	0	0	0	0	0	0	0

World War, and the development of roads and agriculture, have increased concurrently. On the Pare Mountains, roads are relatively undeveloped, and motor transport is, and was, virtually absent in this area. It is probably the strong winds, blowing up from the Mkomazi valley, that are chiefly responsible for carrying the mosquitoes into the mountains. Mosquito densities in huts suggest that some transmission was occurring in a few villages on the upper slopes of the Pare Mountains before huts in the plains were treated with dieldrin, although little or none occurred above the escarpment. Residual spraying in the plains greatly reduced anopheline infestation in huts on the mountains, and has therefore indirectly protected the inhabitants from the risk of malaria infection.

I am indebted to Mr. J. D. Phipps for his help during the three years of observations, and to Dr. D. Bagster Wilson for valuable criticism.

Paper Electrophoretic Separation of the Proteins of Some Leguminous Seeds

The plant materials examined during this work were acetone powders prepared from lentils (*Lens esculenta*, Moench), 'horse' beans (*Vicia faba*, L.), lupin seeds (*Lupinus termis*, Forsk) and fenugreek seeds (*Trigonella foenum-graecum*, L.). Each acetone powder was extracted separately with 0·1 *N* borax–phthalate buffer at *p*H 8·0, the proportion being 10 gm. of acetone powder to 60 ml. of buffer. Extracts obtained in this way were subjected to paper electrophoresis on Whatman No. 1 filter paper in a Shandon horizontal tank. Borax–phthalate buffer, which was prepared by mixing 0·1 *N* borax and 0·1 *N* potassium hydrogen phthalate (*p*H 8·0), was used. A potential of 150 V. was applied for 12 hr. The protein bands were dyed with azocarmine *B* solution according to Turba and Enenkel's method[1].

Four coloured bands (designated *A–D*) appeared in the electrophoretic pattern of each of the seed extracts. It was possible, by the use of ammonium sulphate fractionation, to isolate each of the proteins *B*, *C*, and *D* from the extract of lentil seed. Each of the protein fractions was re-precipitated 2–3 times and each of the final precipitates was dissolved in a small volume of borax-phthalate buffer and dialysed against the same buffer. These protein fractions were tested electrophoretically along with a sample of the original extract.

Protein fraction *D* (precipitated in the range 45–54 per cent saturated ammonium sulphate) was orange-red in colour and fluorescent in ultra-violet light. The absorption spectrum was read with a Hilger spectrophotometer and showed maxima at 360, 460 and 550 mμ (Fig. 1), which indicates that this protein is a flavoprotein.

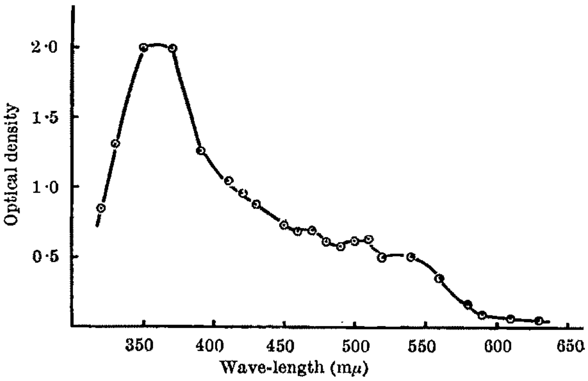

Fig. 1

In order to determine the percentage of each of the protein constituents the filter paper was cut (in a direction perpendicular to the flow of the current) into strips 0·5 cm. wide. Each of the small strips was eluted separately with 5 ml. 10 per cent ammonium hydroxide. The optical density of each extract was determined with a Unicam colorimeter using a filter (Ilford No. 303). By plotting optical density reading against the distance from the point of application of the protein extract to the strip an electrophoretic pattern was obtained. By means of a planimeter, the area under each peak was measured, and in this manner the percentage of the different proteins (in relation to the total proteins in the extract) was assessed. The results (Table 1) indicate that, although the extract of each of the four kinds of seeds under investigation contains the four fractions, the percentage of each of the proteins varies according to the type of seed.

Table 1. Amounts of Various Proteins in Some Leguminous Seeds

Seed	Protein			
	A	*B*	*C*	*D*
Lupinus termis	1·89	86·55	8·79	2·75
Trigonella foenum-graecum	5·26	84·27	5·26	5·26
Vicia faba	5·11	46·51	40·23	8·13
Lens esculenta	3·91	71·02	7·57	17·49

Density-Dependent Factors in Ecology

Solomon and Varley[1] did well to direct attention to the confusion that accompanies the ecological term 'density-dependent factors'. Howard and Fiske's[2] original idea that the multiplication of natural populations of animals can be restricted only by some "factor" that exerts "a restraining influence which is relatively more effective when other conditions favour undue increase" has been extended in a number of directions. I would like to add to Solomon and Varley's etymological criticism of the usage of the term my own criticism of the fruitfulness of the ideas implicit in the term.

It has been argued that only 'biotic factors' can qualify for the class 'density-dependent factors' and hence only competition can limit the numbers of natural populations. Howard and Fiske[2] and Smith[3] qualified this argument but Nicholson[4], and Elton and Miller[5] were more specific. When I tried to confirm the statement by examining the case-histories of a number of populations the ecology of which had been described, I found that there was little correlation between biotic factors and density-dependent factors[6]. The concept of density-dependent factors has also been used as a starting point for mathematical models. The well-known models of Lotka[7] and Volterra[8] have been partly confirmed by laboratory experiments with such simple animals as *Paramecium* but not with more complex ones such as *Calandra* and *Tribolium*, and not with any sort of animal in Nature[9].

Nicholson[10] has published an elaborate mathematical treatment that purports to cover natural populations. His model rests upon the idea of 'equilibrium density' which is analogous to the concept of the 'singular point' in the Lotka–Volterra models. For example, his equation for intraspecific competition, which is one of three basic equations that form the foundation for his model, reads:

$$N_E = \frac{g - lg - wg}{q}$$

where g is the rate of replacement of the 'governing requisite', l is the proportion lost to extraneous influences, w is the proportion lost to individuals that fail to complete the life-cycle through crowding, q is the amount required by one individual to complete its life-cycle and N_E is the equilibrium density.

The value of w depends on the density of the population; above a certain ceiling of density w may be 1; below a certain threshold it may be 0. Solving the equation for values of w between 1 and 0 gives values of N_E between 0 and $\frac{g - lg}{q}$. This does not satisfy the concept of an equilibrium density. On the other hand the equation may be written:

$$N = \frac{g - lg - wg}{q}$$

where N is defined as the density of the population. Then a particular value of N, say N_E, may be designated such that it corresponds to an arbitrary value of w, say w'. But in Nicholson's model the value of w' is defined in terms of N: w' is the value of w which gives $N = N_E$ and there is no other way of defining it. Thus the equation is a tautology. The other two basic equations are subject to similar criticism.

Milne[11] and Nicholson[10,12] argued that only density-dependent factors can keep a population from becoming extinct because, as Elton[13] put it, "the control of populations, i.e., the ultimate upper and lower limits set to increase, is brought about by density-dependent factors". Now if we do an experiment to test a particular null hypothesis such as "this population of species x will not be extinguished by n hours exposure to $t°$ C" we may consider that the negative hypothesis has been disproved if the population is observed to be extinct after we have treated it in this way. (See Fisher's[14] discussion of the null hypothesis.) But if the population remain extant after the experiment we cannot reasonably argue that the population was kept extant by exposure to $t°$ C. for n hours; similarly, with all other environmental components, including density-dependent factors. Moreover, because the argument that only density-dependent factors can keep a population extant depends on the concept of 'ultimate limits' it is not possible to specify a definite time in the null hypothesis that stems from this proposition; this implies that experiments must be continued indefinitely if the null hypothesis is to be disproved[6]. For these two reasons this argument has stultified experiment.

In science an idea may be judged fruitful if it leads to experiment and observation which extend our understanding of Nature. By this criterion the idea of 'density-dependent factors', like the idea of vitalism, seems to have been remarkably fruitless.

Preparation and Sectioning of Tissues embedded in 'Araldite' for Electron Microscope Examination

OWING to the complete lack of polymerization damage and less-stringent hardening conditions, 'Araldite' is being increasingly used as an alternative to butyl methacrylate as an embedding medium in the preparation of tissue for study in the electron microscope. Unfortunately, it has one serious drawback of its own. Unless the consistency of the plastic falls within fairly narrow limits, serious wrinkling is found on sectioning which may make the specimens quite unsuitable for study.

The 'Araldite' components used in the embedding mixture are: 'Araldite' casting resin M, 'Araldite' hardener 964*B*, and 'Araldite' accelerator 964*C*. Dibutyl phthalate is used as a plasticizing agent.

Originally a mixture of casting resin 10·0 ml., hardener 10·0 ml. and plasticizer was used for the initial shakings after fixation in osmic acid and dehydration in alcohol. Soaking times at 48° C. were 3 hr. in a mixture of ½ absolute alcohol, ½ 'Araldite', followed by three soakings of 3 hr. each in 'Araldite' alone. 0·4 ml. accelerator was then added to the mixture and the tissue was left to soak at room temperature for 12 hr. before the final embedding at 48° C. in accelerated 'Araldite'. The capsules were hardened at 48° C. for about 72 hr. before cutting.

It was early found that even a moderate increase in the concentration of accelerator produced a very hard and brittle block. It was possible to produce thin sections from such a block, but they invariably showed severe wrinkling, and it is now usual to discard any blocks which are found to be brittle during preliminary trimming. Reduction of accelerator produced plastic of a consistency that would cut without wrinkling, but this only applied to the supporting block. The tissue itself was often exceedingly soft and pasty, and it was obvious that the 'Araldite' had not penetrated in desirable concentrations. As it was known that the tissue could be hardened by additional accelerator it was suspected that the casting resin rather than the hardener was failing to penetrate, and this view was supported by the fact that the hardener is by far the less viscous of the two. As a result the soaking times were greatly prolonged, and the concentration of the casting resin in the early mixtures was increased. The concentrations used in the first soakings are now : casting resin 15 ml., hardener 5 ml., plasticizer 1 ml. After fixing and dehydration the tissue is soaked at 48° C. in a mixture of ½ absolute alcohol, ½ 'Araldite' for 6 hr., and then in pure 'Araldite' for 72 hr., the mixture being changed every 24 hr. The soaking is then continued for another 72 hr. in a mixture of casting resin 10 ml., hardener 10 ml. and plasticizer 1 ml., the resin again being changed every 24 hr. 0·3 ml. accelerator is then added for a 24 hr. soak at room temperature followed by the final embedding in a fresh accelerated mixture. With only 0·3 ml. accelerator hardening times at 48° C. are increased, and it is not unusual for the blocks to require baking for a week before they are suitably hard. Even now preliminary trimming may show the tissue to be undesirably soft, but further baking of the untrimmed capsules produces little improvement. If, however, the block is trimmed to expose the tissue in a small pyramid of soft plastic, further baking at 48° C. for 2–3 days will cause satisfactory hardening to a cutable consistency.

This embedding procedure has been successfully used on a variety of tissues, including pituitary, liver, various tumours, and striated muscle ; but even now it is rare to produce sections without a trace of wrinkling. Birbeck and Mercer[1] found that a narrow knife angle and very slow passage of the block across the blade would reduce wrinkling, as would the reduction of the cutting area of the block to very small dimensions. This has also been our finding, but with 'Araldite' it is often possible to obtain thin sections of up to 1 mm. square, and the increase in viewable tissue area is a great advantage. In these conditions, it is usually found that the portions of the section cut last show wrinkling, but this can largely be counteracted by trimming the block to rectangular shape and cutting with one long side to the blade.

During the period of this work I was in receipt of a grant from the British Empire Cancer Campaign.

A Simple Micro-Stirrer

A simple micro-stirrer has been developed for micro-analyses involving quantities of fluid varying from 1 ml. down to small drops of fluid which are titrated on waxed slides. Its main advantages over previous methods of micro-stirring are that it is cheap and relatively simple to make and can be controlled to give almost instantaneous even mixing without splashing or bubbling. It is therefore particularly suitable for continuous stirring while performing potentiometric or colorimetric titrations.

The stirrer (Fig. 1) consists of an electric bell assembly driven by means of a small domestic bell transformer which is tapped to give 3, 5 and 8 volts. For potentiometric titrations the bell is removed and a piece of stiff piano wire is attached to the hammer arm by means of a tight-fitting polyethylene sleeve. The piano wire is flattened at the sleeve end to prevent it turning and is then bent downwards through an angle of 90°. A piece of 'Tufnol' insulates the wire from the bell mechanism. The other end of the piano wire carries a small chuck, which holds a paddle-shaped electrode.

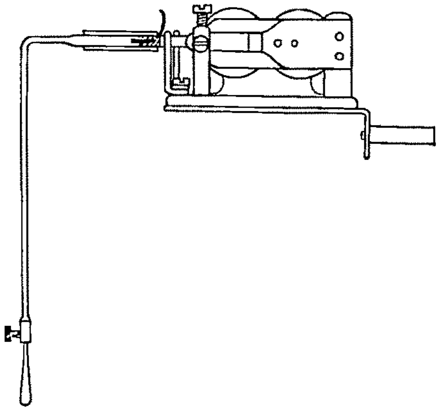

Fig. 1

Even and splashless stirring is obtained by limiting the travel of the hammer arm by means of two movable stops, one on each side of the arm. The high-frequency vibrations are transmitted and amplified by the whip of the stirring arm, the lateral vibrations of which should be very small to obtain the desired type of stirring. The amplitude of these vibrations is controlled by the length and stiffness of the wire, while their frequency can be altered by varying both the voltage energizing the bell and the setting of the interruptor set screw. For colorimetric titrations, particularly those carried out in an absorptiometer, a small glass paddle is recommended.

Salt Excretion in Marine Birds

May I add a further observation to F. S. Russell's interesting communication under this title[1] ? More than thirty years ago I noticed a similar thing in the giant petrel or stinker (*Macronectes giganteus*) of the southern oceans, and published[2] an account of it, though not in a scientific paper, in 1951 : "When [a flying stinker] is right alongside and you can see him plainly, nearly always you will notice that he has a drop on his nose ; hanging from the tip of the hook at the end of his beak is a drop of something—whether water or some other fluid I know not". This, too, was evidently salt excretion in action.

PSYCHOLOGY

Colour Vision Phenomenon of a New Class

If one looks toward a bright field of white light (white cloud or white fluorescent lamp), interposes an orange Wratten No. 21 filter for 5 sec., then removes the filter, a bright, saturated greenish-yellow pattern is seen. It is of irregular, blotchy shape and persists for 1–2 sec.

The hue and saturation of the pattern remain unchanged despite wide variation in choice of filter used in step 1. (Step 1 is the 5-sec. period in which an orange filter or the equivalent is used ; step 2 is the 1–2-sec. period in which the pattern is seen.) Instead of the orange Wratten 21 filter, any filter that transmits much 540–590 mμ light and no light of wave-length below 490 mμ may be used.

In step 2, instead of using no filter, any blue, green, yellow, orange, purple or grey filter that has appreciable transmittance near 470 mμ may be interposed.

To predict whether a filter will succeed in step 1, the spectral transmittance curve of the filter must be examined. The colour of the filter may not be indicative. (I have a pair of orange filters that are almost identical in colour but behave oppositely, one succeeding in step 1 and the other in step 2.)

Moderately high intensity is required in step 1. The intensity of a white cloud or a bare white fluorescent lamp is very satisfactory. A heavily overcast sky, or a sheet of white paper resting on the top of a desk, may be too dim.

The intensity and quality of the step 1 illumination determine whether the pattern will be seen (in the subsequent step), but do not govern the brightness or colour of the pattern.

It is the step 2 illumination that governs the brightness and colour of the pattern. If the step 2 illumination consists of white light, the pattern appears greenish-yellow, and the brightness is roughly proportional to the intensity of the white light. If the step 2 illumination consists of just 400–500 mμ light, the pattern appears green. If the step 2 illumination contains 400–500 mμ light and also light in longer wave-length bands, the hue appears intermediate between green and the hue one normally associates with the longer wave-length bands. For example, the illumination obtained with the aid of a white fluorescent lamp and a reddish-purple filter transmitting in the two bands 400–500 mμ and 600–700 mμ leads to a pattern that is midway between green and red, namely, orange.

If the step 2 illumination is of zero intensity, the pattern does not appear. (Various after-images appear, but seem unrelated to the pattern under discussion.)

The pattern has an irregular, blotchy shape, and very different shapes may be noticed in successive trials. The size of the pattern may decrease markedly from one trial to the next, and, after four or five trials made within a period of one minute, the pattern may entirely fail to appear. In the first trial the pattern may have an angular width of 40–80 deg., and the fovea and macula regions may participate ; in subsequent trials the pattern becomes less extensive, and the fovea and macula regions may fail to participate. The grain size, or resolution, of the pattern is low, being perhaps 0·1–0·5 deg.

After resting his eye for 10 min. the observer may see the phenomenon again. Resting does not require dim light or darkness ; it requires merely the avoidance of light that is devoid of energy in the 400–500 mμ range. Looking through any step 1 filter is tiring, but looking through any step 2 filter is not. Thus tiring, too, depends on the transmittance curve of the filter rather than on its colour.

In the first trial (that is, when the eye is fresh), the duration of step 1 may be reduced ; the 5-sec. duration is not necessary, and durations as short as 2 sec. (sometimes even ½ sec.) suffice. Moreover, the intensity of the pattern afterwards seen is independent of the step 1 duration.

When the pattern disappears (after 1–2 sec. of step 2 illumination), it does not fade gradually and uniformly, but disappears piecemeal, each piece disappearing suddenly.

Each eye acts independently. One eye may become tired and the other (not exposed to step 1 illumination) may remain fresh. Indeed, the different regions of a single eye appear to act independently. Accordingly, split-field experiments are feasible. For example, in step 2 the patterns produced by two unlike filters held side-by-side a few inches in front of the eye may be compared.

A blue or magenta pattern is sometimes observed in step 1 if this step is prolonged for 5–15 sec., and this pattern sometimes has a shape similar to that of the pattern afterwards appearing in step 2. (I am indebted to my colleague E. S. Emerson for pointing this out.)

Approximately fifty of my friends have tried to see the greenish-yellow pattern by the method indicated in the first paragraph, and more than forty succeeded.

The new phenomenon has little in common with the usual adaptation, fatigue, or complementarity phenomena. Such phenomena usually involve smooth fields, dim and unsaturated colour, slow build-up and gradual fading. Also, the hues perceived usually change when the hues of any of the exciting fields are changed, and they are similar when exciting fields are similar in colour. The new phenomenon exhibits very different tendencies which are suggestive of abrupt switching mechanisms.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, January 19

Royal Geographical Society (at 1 Kensington Gore, London, .W.7), at 5 p.m.—Prof. A. L. Banks: "The Study of the Geography f Disease".

Institution of Electrical Engineers, Radio and Telecom- unication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—r. A. H. W. Beck: "High-Current Density Thermionic Emitters".

University of London Institute of Education (in the Assembly all, Malet Street, London, W.C.1), at 5.30 p.m.—Dr. W. Mays: Piaget's Theory of Intellectual Development".*

British Computer Society (at the Northampton College of dvanced Technology, St. John Street, London, E.C.1), at 6.15 p.m. -Mr. D. C. Hemy: "The Study of the Application of a Computer Production Control".

Institute of Metal Finishing (at Northampton College of Ad- anced Technology, St. John Street, London, E.C.1), at 6.15 p.m.—r. P. Eisler: "Printed Circuits—Some Metal Finishing Methods sed on Foil-Clad Laminates in Electronic Production".

Royal Institute of Chemistry, London Section (at Enfield echnical College, Queensway, Ponders End, Enfield), at 7.30 p.m.—r. A. S. Curry: "The Chemistry of Poisoning".

Monday, January 19—Thursday, January 22

Physical Society (at the Royal Horticultural Society's Old and ew Halls, Westminster, London, S.W.1)—Exhibition of Scientific struments and Apparatus.

Discourses:

onday, January 19

At 5.45 p.m.—Mr. R. S. Pease: "The Physics of Controlled Thermo- uclear Fusion".

uesday, January 20

At 5.45 p.m.—Dr. Robert Page: "Frontiers of Space".

Vednesday, January 21

At 5.45 p.m.—Mr. J. G. D. Pratt: "Physical Science in the Trans- ntarctic Expedition", introduced by Sir Vivian E. Fuchs.

Tuesday, January 20

Bone and Tooth Society (at the Institute of Orthopædics, 234 reat Portland Street, London, W.1), at 4.30 p.m.—Symposium on Epiphysial Growth".

British Museum (Natural History) (in the Chemistry Lecture heatre, Imperial College of Science and Technology, Exhibition oad, London, S.W.7), at 5.30 p.m.—Dr. Isles Strachan: "Darwin d Palæontology" (Swiney Lectures on Geology).* (Further lectures January 22, 27, 29, February 3 and 5.)

Institution of Electrical Engineers, Measurement and ntrol Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—iscussion on "D.C. Amplifiers" opened by Mr. K. Kandiah.

British Glaciological Society (at Bedford College, Regent's rk, London, N.W.1), at 6 p.m.—Prof. R. Finsterwalder (Munich): he International Glaciological Expedition to Greenland".

Plastics Institute, London and District Section (at the Well- me Building, 183–193 Euston Road, London, N.W.1), at 6.30 p.m. Prof. M. G. Stacey, F.R.S.: "Fluorine Containing Polymers".

Wednesday, January 21

Royal Society of Arts (at John Adam Street, Adelphi, London, .C.2), at 2.30 p.m.—The Right Hon. Lord Nathan, P.C.: "Tech- cal Education—a Prognosis".

Royal Meteorological Society (at 49 Cromwell Road, London, W.7), at 5 p.m.—Mr. F. A. Berson: "Some Measurements on ndercutting Cold Air"; Mr. R. A. Hamilton: "The Meteorology North Greenland During the Mid-Summer Period" and "The eteorology of North Greenland During the Mid-Winter Period".

Royal Statistical Society (at the London School of Hygiene d Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), 5.15 p.m.—Mr. K. S. Lomax: "Production and Productivity ovements in the U.K. since 1900".

Institution of Electrical Engineers, Radio and Telecom- nication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—r. C. G. Garton: "Dielectric Materials—Trends and Prospects".

Institution of Mechanical Engineers, Applied Mechanics roup (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m. Discussion on "Trouble with Vibration".

Royal Institute of Chemistry, London Section (joint meeting ith the London Section of the Society of Chemical Industry, University College, Gower Street, London, W.C.1), at 6.30 p.m.—Eric Rideal, F.R.S.: "The Impact of Colloid Science on Tech- logy".

Society of Chemical Industry, Food Group (joint meeting with e Oil and Fats Group, at Brunel College, Acton), at 7 p.m.—of. A. C. Frazer: "The Biological Effects of Polyoxyethylene sters".

Thursday, January 22

University College (in the Anatomy Theatre, Gower Street, ndon, W.C.1), at 1.15 p.m.—Mr. B. C. Brookes: "The Limits of e Popularization of Science".*

University College, Department of Biochemistry (in the Physiology Theatre, Gower Street, London, W.C.1), at 5 p.m.—Prof. F. G. Young, F.R.S.: "Hormones and Metabolic Processes"*. (Further lectures on January 29 and February 5).

Thursday, January 22—Friday, January 23

Institute of Physics (in collaboration with the British Nuclear Energy Conference, in the Lecture Theatre of the Institution of Civil Engineers, Great George Street, London, S.W.1), at 2.30 p.m. on Thursday and 9.30 a.m. on Friday—Symposium on "Nuclear Fuel Cycles".

Friday, January 23

British Psychological Society, Occupational Psychology Section (in the Department of Psychology, Birkbeck College, Malet Street, London, W.C.1), at 1 p.m.—Mr. M. J. Kirton: "Some Aspects of Current Research on Management Initiative".

Biochemical Society (in the Department of Chemistry and Bio-chemistry, St. Thomas's Hospital Medical School, London, S.E.1), at 2 p.m.—379th Meeting.

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 2.15 p.m.—Geophysical Discussion on "The Automatic Reduction of Geophysical Data". Chairman: Sir Edward Bullard, F.R.S. Speakers: Mr. G. A. Corby, Mr. A. Dennison, Mr. G. W. Lennon, Mr. R. H. Merson, Mr. C. M. Minnis and Mr. M. J. Tucker.*

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. H. R. Howells: "Marine Refrigeration" (Thomas Lowe Gray Lecture).

Manchester Statistical Society, Industrial Group (in the Portico Library, 57 Mosley Street, Manchester), at 6 p.m.—Dr. M. G. Simpson: "Operational Research in the Coal Industry".

British Institution of Radio Engineers, London Section (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Inaugural Meeting of the Institution's Medical Electronics Group. Address by Prof. A. V. Hill, F.R.S.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Keeper (with a university degree or the Diploma of the Museums Association, specialized in some branch of zoology or botany, a wide general knowledge of natural history, and preferably experience of museum work) of the Department of Biology—The Director, Museum and Art Gallery, New Walk, Leicester (January 31).

Lecturer in Biochemistry—The Secretary of University Court, The University, Glasgow (January 31).

Research Assistant in the Department of Physics for post-graduate studies in electron diffraction and microscopy, leading if desired to a higher degree—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (January 31).

Senior Lecturer in Mechanical Engineering—The Registrar, The University, Sheffield (January 31).

Senior Lecturer (with a good honours degree and teaching experience) in Applied Mathematics, and Lecturers (2) (with a good honours degree and teaching experience) in Mathematics at the Nigerian College of Arts, Science and Technology—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (February 4).

Senior Lecturer or Lecturer (with special qualifications in pure mathematics) in Mathematics—The Registrar, The University, Manchester 13 (February 7).

Chair of Microbiology in the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 12).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Engineering, Pharmacology or Physics—The Secretary, The University Aberdeen (February 13).

Senior Lecturer in Obstetrics and Gynæcology at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong, February 15).

Lecturer (preferably interested and with research experience either in Western industrial societies or in Africa) in Anthropology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 16).

Lecturer (with an honours degree in geography) in Geography at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 16).

Senior Lecturer in the History and Philosophy of Science at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 16).

Halliburton Chair of Physiology tenable at King's College—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 17).

Lecturer in Philosophy at the University of New England, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 20).

Demonstrator (with interests in human geography, preferably economic geography) in the Department of Geography—The Secretary of the Appointments Committee, Department of Geography, The University, Downing Place, Cambridge (February 21).

Lecturer in Applied Mathematics (Digital Computing)—The Secretary, The Queen's University, Belfast (February 28).

Chair of Veterinary Medicine or Chair of Veterinary Surgery, in the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, March 9).

Research Fellow or Fellow in the Department of Statistics, Research School of Social Sciences, Australian National University, Canberra, to work in the field of mathematical statistics and its applications to other sciences—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, March 16).

Chair of Philosophy in the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, March 31).

Senior Lecturer in Physics at Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, March 31).

Assistant Professor of Biology, to give instruction in physiology, embryology and histology—The Head, Department of Biology, Memorial University of Newfoundland, St. John's, Newfoundland.

Graduate Physicists (with a first or good second) for research into either (*a*) the solution of scientific and technical problems by the use of all types of radioisotope techniques; or (*b*) the development of new measuring techniques for radioactive materials and ionizing radiations and the investigation of limits of performance of detectors—The Group Recruitment Officer (1270/34), United Kingdom Atomic Energy Authority, A.E.R.E., Harwell, Berks.

Laboratory Technician (male or female, with experience in biology and interested in animals)—The Secretary, Furzedown College, Welham Road, London, S.W.17.

Lecturer in Applied Physics, to assist in establishing Higher National Certificate courses in Applied Physics—The Principal, Farnborough Technical College, Boundary Road, Farnborough, Hants.

Lecturer (man or woman, with an honours degree in physics and preferably a teaching qualification) in Physics at the Medical School, Kano, Northern Nigeria, to teach to advanced level—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.117/408/030.

Lecturer (preferably with an active interest in research, together with teaching and/or industrial experience) to teach Physical Chemistry to the standard of the Diploma of Technology, B.Sc. (Special) Chemistry and A.R.I.C.—The Principal, College of Technology, Queen Street South, Huddersfield.

Principal (preferably under 50, with a degree in engineering or applied science or professional equivalent, together with wide experience of technical education) of the recently established Institute of Technology, Jamaica—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.114/32/09.

Professor of Mechanical Engineering, and a Lecturer in Electrical Engineering (Electrical Power) at the University of Ceylon—The Ministry of Labour and National Service (E.9), 26–28 King Street, London, S.W.1, quoting E.9/TCS/216-7CEY.

Scientific Officer (honours graduate, preferably in biochemistry or physiology), to work, both in laboratory and with experimental animals, on nutritional problems in pigs—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 59/1.

Technician (preferably with previous experience) for the Chemistry Laboratories—The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey.

SP. 500 SPECTROPHOTOMETER

186 mμ

The Unicam SP.500 Ultraviolet and Visible Spectrophotometer is now fitted with a high grade silica prism which extends the useful working range of the instrument beyond 200 mμ to the region of atmospheric absorption at 186 mμ.
Better prism transmission gives the important advantage of reduced slit widths with a consequent reduction in stray light and increase in resolution, a facility which is especially valuable in the 190-240 mμ region.
A redesigned slit mechanism, in which static friction is virtually eliminated, allows the lowest slit widths to be accurately set and reproduced. Combined with the better transmission of the new prism, this feature greatly increases the scope of the instrument for high resolution determinations at the lower end of the spectral range.

THE STRUCTURE OF GLASS

Proceedings of a Conference on the Structure of Glass held in Leningrad

Issued by

The Institute of Silicate Chemistry of the Academy of Sciences of the U.S.S.R.

294 *pages* *Illustrated* 168*s. net*

This translation, by E. B. Uvarov, was sponsored jointly by the American Ceramic Society and the National Science Foundation and offers the Western scientist a general look at the status of glass science in its many aspects. Although the Conference was held a few years ago, the work does not appear dated: the factual portions comprise a definite contribution to the knowledge commonly available, and the controversial portions will add zest to those concerned with the yet unsolved riddle of the structure of glass.

THE DESIGN OF PHYSICS RESEARCH LABORATORIES

A Symposium

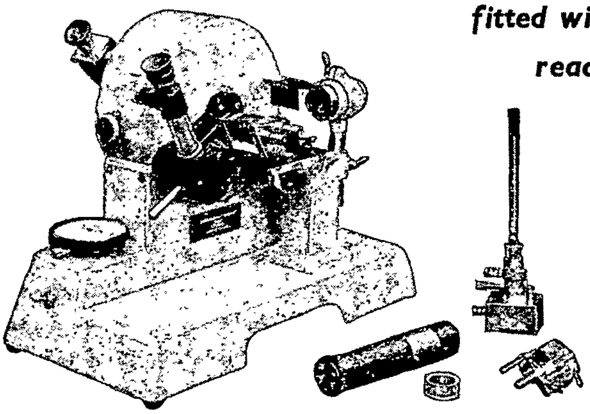
108 *pages* *Illustrated* 21*s. net*

The symposium was primarily devoted to the design of physics research laboratories, but much of the information in the papers, and in the account of the discussion here published, have a wider application and will be of value to all concerned with the design of science laboratories in general.

37 ESSEX STREET, LONDON, W.C.2

PRECISION INSTRUMENTS

Pulfrich Refractometer



fitted with circle divided on glass and giving readings on opposite sides of the circle to 5 seconds, by double microscope

This instrument possesses many advantages ove the older type of Pulfrich refractometer and is use in all parts of the world for testing oils, optic glass, chemicals, drugs, etc.

We shall be pleased to demonstrate this instrument and give any advice as to its use, by appointment at our Works.

NATURE CONSERVATION AND ECOLOGICAL RESEARCH

IN a country so thickly populated as Britain, the sequestration of land for purposes other than those of immediate economic or social advantage inevitably presents serious problems, of which the expenditure of public money on the project is but one. In response, however, to the recommendations of the reports of the Wild Life Conservation Committees which were published in 1947[1,2] there was established the Nature Conservancy, with the express intention that it should acquire and maintain land where it is regarded as necessary for the conservation of the flora and fauna, direct research on the ecology of the wild life of Britain and act as a clearing house for advice and information in relation to any problems which may arise in this ecological field, whether within its reserves or elsewhere in the country. It being recognized that such a service is primarily dependent upon long-term research, the wise decision was made that the Conservancy, like the Agricultural Research Council, the Department of Scientific and Industrial Research and similar bodies, should be responsible to Parliament, not through any departmental head, but direct through the Privy Council and its Lord President.

Despite having had barely ten years of functional existence, the Nature Conservancy has pursued a vigorous policy of implementing the major recommendations of the Wild Life Conservation Committees, which were embodied in the terms of reference under which the Conservancy was established. Thus, it now possesses or controls some 125,000 acres of land as National Nature Reserves, and may be regarded as approximately half-way towards attaining a final target comprising some 140 areas of land of the most diverse ecological interest. In addition, two field research stations, Merlewood at Grange-over-Sands and Furzebrook near Wareham, have been equipped; smaller provision of laboratories and equipment has been made at some of the reserves; while a system of regional officers exercises an all too slender integration of interests between the Conservancy and land-owners and land-users throughout the country.

The Select Committee on Estimates has recently[3] subjected the affairs of this youngest of our scientific services to scrutiny and has expressed its satisfaction with the potential value to the country of its work. To the scientific ear there is an oddly parochial ring to the qualification: "It is important that wisdom and common sense are brought to bear in selecting projects for research which will redound to the prestige and prosperity of the nation". But we may rest assured that so small an objective will be achieved within the framework of the Conservancy's policy of enlarging our knowledge of the ecology of the British Isles, and it is a matter for satisfaction to biologists that this framework has received approval. The Select Committee's sympathetic appreciation contains four major reservations. Of these, two relate to the administrative organization of the Conservancy and can be left for adjustment to the domestic wisdom of those immediately concerned. The other two, however, relate to scientific policy and call for some comment.

It is a matter of concern to the Select Committee that on one hand the Conservancy is committed to a policy of increasing substantially, and as rapidly as possible, its holding of nature reserves, while on the other the provisions for staffing and maintaining some of those already acquired are very thinly spread. The Committee accepts that it is vital to complete as early as possible the programme of dedication of National Nature Reserves, if only to secure that too much is not lost to the demands for development which are being actively pressed by many interests. But it foresees, with some alarm, that management of the new reserves, even in a manner comparable only with that of existing areas, must result in the presentation of bills for equipment, maintenance and staff which must swell the Conservancy's annual budget by considerable sums. Moreover, the visiting sub-committee which inspected Moor House Reserve in Westmorland was clearly appalled by the difficulties and hardships suffered by workers there, with no telephonic communication and only a badly surfaced seven miles of moorland track and a 'Land Rover' as their link with civilization. It may be commented in passing that such conditions, while clearly difficult for the administrator and the lay worker, may be regarded as almost normal by the field biologist, and indeed such remote isolation is eagerly sought by them for the freedom from interference and interruption by the public which they offer.

The solution to the problem offered by the report of the Select Committee is the recommendation that existing reserves be given prior claim on finance both for maintenance and for research, except where it appears that a newly acquired reserve may be liable to deteriorate in scientific value unless it is adequately staffed and managed. This same problem of provision of, in particular, scientific staff is evidently in mind in the subsequent suggestion, that greater efforts be made to induce the universities to play a larger part in the ecological investigations of the Conservancy. It is not, of course, within the terms of reference of the Select Committee to recommend expenditure beyond the estimates which are under consideration. It is, however, difficult to escape the conclusion that this may become necessary if the Conservancy is to play its proper part. At present we spend annually something of the order of twopence a head of population on its work, and this figure will rise to nearly threepence by the time the programme of acquisition of reserves had been completed. This by any standard cannot be described as extravagant, and contrasted with expenditure on parallel projects in the United States and elsewhere it is conservative. Moreover, by virtue of our situation on the seaboard of Europe and, above all, of the extreme geological diversity to be found within so small a compass within the British Isles, it is probably true that ecological conditions present a far broader variety here than is to be found in close proximity almost anywhere else in the world. It follows that, to achieve its primary object of understanding the ecology of Britain, the Nature Conservancy must be able to prosecute at one and the same time active research in a number of different reserves. It is true that attainment of such an objective is far distant, and inevitably priorities must be determined. It is also true, however, that the pace and intensity of human interference with natural conditions have increased out of all measure during the past fifty years, and is still increasing. It is therefore most urgent that we should endeavour to obtain at least an inkling of the effects of our activities upon the world around us, and for this we need a yardstick in the form of some documentation of the conditions in those areas which have suffered least interference by man, and still remain to us. A substantial increase in the annual budget of the Nature Conservancy may well, therefore, prove a long-term economy in saving us from the ecological mistakes the cost of which in the past may be readily appreciated from a perusal of Mr. C. S. Elton's latest book[4].

A strengthening of the link between the Conservancy and the universities will undoubtedly be welcomed by both parties. There are, however, difficulties which must be faced. In most universities the disciplines cognate to ecological research tend to be departmentally isolated, and the workers themselves are for the most part unused to the discipline of team-work such as is demanded by most of the Conservancy's major projects. In addition, too, many senior workers are caged by administrative and teaching duties to such an extent that they are rarely free to undertake full ecological investigations, most of which demand freedom to attend to them in the field throughout the year. This handicap becomes particularly forceful where the region of study is, as are most of the National Nature Reserves, remote from the individual's laboratory. It follows that the conscientious university teacher must, if he is interested in ecology, do a great deal of his work by proxy, building up a school of young research workers under his inspiration and guidance. This immediately brings back the problem of finance. Now the Nature Conservancy at present spends about 10 per cent of its annual budget, namely, some £30,000, in subventions for ecological research by university and other workers outside its immediate orbit. This, in 1957, enabled the Conservancy to support sixteen senior university workers and some thirty postgraduate students ; but owing to financial stringency it was impossible to consider making any new grants during the year despite requests in relation to a number of important projects. It seems, therefore unrealistic to expect increased co-operation from universities, the resources of which are already overstrained, in the absence of any means of providing the financial support this demands.

It is necessary to join issue with the Select Committee over its recommendation 19 on the subject of revenue. This postulates that the Conservancy should make greater efforts to obtain revenue from its reserves and, by implication, should instruct its regional officers to give time and thought to devising means of deriving some income from the reserves in their charge. It cannot be too strongly emphasized that the functions of the Nature Conservancy are those of research, conservation and advice ; its regional officers provide the main lines of liaison in relation to these services, while the reserves are its laboratories. These officers are few in numbers and each is already fully occupied with a large area in which to exercise a variety of delicately adjusted functions. None is by training as equipped to deal with the commercial transactions envisaged as is the land agent, and it would severely handicap them in the performance of their scientific duties were they called upon to look for revenue from their reserves.

On the larger issue, that the Conservancy should be expected to seek to derive profit from its lands ; first, it must be realized that most of the land on which reserves are situated is very poor, this being one of the major reasons underlying its selection. But apart from this, it is not the function of research laboratories to make money out of side activities, and it would seriously handicap the progress of original investigations should such a duty be imposed upon them. This is not to suggest that where a market exists for the end-products of the normal research and maintenance activities carried on, this should not be exploited. Indeed, the officers of the Conservancy have produced evidence that a small revenue is derived from sales of timber and the like and from grazing. This must, however, be allowed to remain incidental to the scientific management if the reserves are to be efficiently maintained. It is frequently necessary to extinguish sporting rights and to modify the management of land in order that a natural—or more natural—balance may establish itself for the purposes of the scientific investigations, the results of which will provide ultimately a true profitable return in an increased knowledge of the causes which underlie natural processes and the results of our maltreatment of them.

CHARACTERISTICS OF THE BARTONELLAS

Morphologische, Biologische und Serologische Eigenschaften der Bartonellen

Von Dr. Reinhard Wigand. Pp. viii + 71. (Stuttgart: Georg Thieme Verlag, 1958.) 7.80 D.M.

THIS book is not a monograph on bartonellas, which, by the way, would be most welcome. It gives a detailed record of the author's own work on the subjects mentioned in the title.

Electron microscopical studies have mainly confirmed early observations. They have, however, made possible precise measurements of the various members of the group. (The reader should note a printing error: the flagella of *Bartonella bacilliformis* are not 20μ thick as stated on p. 23.) The cytochemical studies have shown that both *Haemobartonella muris* and *Eperythrozoon coccoides* contain ribonucleic and deoxyribonucleic acids. The conclusion concerning the structure of their outer layer is somewhat obscured by the fact that Wigand uses the term membrane loosely, and not in the modern sense, as opposed to bacterial wall. The study of the action of antibiotics is reported in detail and the tables giving the comparative sensitivity of various bartonellas to antibiotics are certainly useful. So far as infection with *H. muris* is concerned, the statement that a complete picture of infection is observed only in splenectomized mice is not valid. The work of Gledhill and Andrewes concerning the co-operative action of *Eperythrozoon* and of the virus of hepatitis could perhaps have been quoted in the discussion of the pathogenic activity of *Eperythrozoon*.

The demonstration by Wigand of a serological relationship between *H. muris* and *Eperythrozoon* is important. It was predictable since a typical *Eperythrozoon* phase has been recognized in *Haemobartonella canis* (which should have been mentioned in the book). This poses the problem of the 'round' form of *Bartonella bacilliformis* observed by Noguchi and which is interpreted by Wigand as the result of a degeneration. The bodies observed by Noguchi, however, are indistinguishable from typical *Eperythrozoon* and are not to be confused with the coccoid forms of involution so easily observed in bartonellas, or in any other bacteria. It is clear that if an *Eperythrozoon* phase exists in the life-cycle of the human *Bartonella*, the problem of its affinities would have to be reconsidered.

Wigand has not been able to detect serological relationships between *Eperythrozoon* of the mouse and *Anaplasma* of the bovines. It seems perfectly justifiable, however, to conclude, with Wigand, as was already done in 1931 by Lwoff and Vaucel, that the two organisms are related.

According to Wigand, *Bartonella* is a bacterium. *Haemobartonella*, however, is supposed to lack any of the typical features of bacteria. It is neither a virus nor a protozoon. For Wigand, they resemble the pleuropneumonia group of organisms. But these, being bacteria, certainly possess some features of the Schizomycetes group. If *Haemobartonella* and *Eperythrozoon* are pleuropneumonial-like organisms they should also possess bacterial characteristics. Otherwise, they would belong nowhere. Finally, the reader is puzzled by Wigand's statement that *Hæmobartonella* and *Eperythrozoon* are devoid of a membrane, of an internal structure and of cellular organization (p. 26). How these strange creatures, which, by the way, are extracellular parasites, manage to grow, to multiply true to type and to survive, is a mystery. The very existence of *Haemobartonella* and *Eperythrozoon* would, in my opinion, make it probable that, like all other organisms, they do have a cellular organization.

Despite the absence of index, the specialists on *Bartonella* and *Haemobartonella* will find in this book a number of useful technical, electron-microscopical, chemotherapeutical and serological data.

A. LWOFF

COLORIMETRY IN BIOCHEMISTRY

Colorimetric Analysis

By Noel L. Allport and Dr. J. W. Keyser. Vol. 1: Determinations of Clinical and Biochemical Significance. Second edition. Pp. xi + 424. (London: Chapman and Hall, Ltd., 1957.) 50*s*. net.

COLORIMETRIC analyses, using photoelectric apparatus to measure the intensity of transmitted light, are nearly always superior to gravimetric or titrimetric methods in speed of assay and in the avoidance of the exercise of personal judgment in making the final readings. Moreover, the cleaning and maintenance of apparatus are usually simpler in the case of colorimetric methods. It is not surprising, therefore, that in clinical biochemical work colorimetric methods are often the methods of choice; their slight inferiority in accuracy, in some cases, being offset by their suitability for the performance of large numbers of routine assays.

In the volume under review Mr. N. L. Allport and Dr. J. W. Keyser have given us a collection of about one hundred colorimetric techniques, covering a much wider range than that usually needed in clinical work. This volume is an extension and revision of section three of the first edition, published in 1945, which dealt with analyses of clinical and biochemical significance. The number of analyses described has been increased about threefold. Among the additions specially likely to interest the clinical chemist, assays of adrenocortical steroids, bromsulphthalein, congo red, dextran, dinitro-orthocresol, Evans blue, inulin, protein-bound iodine, acid optimum phosphatase activity and urobilinogen should be noted.

As in the first edition, description and discussion of colour-measuring apparatus have not been included. The critical selection of material, valuable discussion of each method, and clarity of presentation which were striking features of the first edition have been fully retained.

The wide range of analyses covered adds greatly to the general interest of the book. The clinical chemist should find here many suggestions for additions to his established routine and for techniques which show improvements on the older methods.

Colorimetric methods cannot always be the methods of choice. This is recognized and indicated where necessary, as, for example, in the description of the assay of calcium in serum, where the well-established and straightforward titration of the precipitated calcium oxalate receives due recognition.

In the section dealing with the assay of carbon monoxide in blood, a good feature is the inclusion of the old, but simple and reliable, tannic acid technique. However, the titrimetric technique using the Conway micro-diffusion unit, and based upon the liberation of hydrochloric acid from palladium chloride by carbon monoxide, would probably be the method of choice in most clinical laboratories.

One wishes that the important question of the assay of adrenaline and noradrenaline in urine could have been discussed in the section on adrenaline assay. In recent years clinicians have shown a keen and very understandable interest in this assay, because it is a valuable diagnostic aid for investigating patients suspected of harbouring a phaeochromocytoma. While assay by the cat blood pressure technique is probably the method of choice, many laboratories have no facilities for this procedure. Colorimetric methods have been described, but only techniques involving measurement of fluorescence in ultra-violet light seem at present to be adequate.

In the section dealing with the assay of uric acid in blood no mention is made of the simple procedure of Benedict and Behre for removing the interfering substance thioneine from blood filtrates. Doubtless the authors consider this refinement unnecessary for both the methods they quote, but it should be borne in mind by all concerned with this assay.

An appendix to this book gives, with references, a list of thirty-two further methods, not included in the text. A short description of the principle underlying each of these methods is included. Finally, full indexes of authors and subjects conclude a practical and interesting volume which should certainly find a place in the laboratories of all who use colorimetric methods in clinical or biochemical work.

N. R. LAWRIE

AFRICAN APHIDS

A Study of the Aphididae (Homoptera) of East Africa

By V. F. Eastop. (Colonial Research Publications.) Pp. vi+126. (London: H.M. Stationery Office, 1958.) 27*s*. 6*d*. net.

It is surprising that so little attention has been paid to surveys of the aphid fauna in the tropical and subtropical countries of the world in view of the economic importance of this class of insect. This is particularly true of Africa south of the Sahara, where the fauna has never been systematically studied and where, in consequence, many of the names that have been in common use in East Africa have now been found to be wrong. Yet it is of vital importance to the economic entomologist that he should know accurately the identity of the species with which he has to deal if he is to be able to benefit from the experience of others and from what has been recorded about it. Furthermore, in recent years, the Aphididae, as proved vectors of plant diseases, have assumed an even greater economic importance.

The objects of the present work, according to the author, are to provide a means of identifying those aphids known to occur in East Africa, to make possible the identification of those species occurring in adjacent territories that are not known from East Africa at present, and finally to bring together under each species the biological data available.

The foregoing objects have been admirably achieved. The number of known species from the region has been increased from 30 to 80, any one of which can be run down by following the keys which take one through each category of the classification down to species. Mistaken identities of some species are rectified and other species are synonymized. A new species and a new subspecies are described and recognition characters are given in the case of most species. The figures are adequate but their arrangement and that of the legends might have been improved. A list of host plants arranged alphabetically in families and of genera within families will be most helpful in providing an indication of the possible identity of an aphid species and will form the basis of a much more extended list as more knowledge is accumulated. The book is indexed and a comprehensive list of references is supplied.

This is the type of taxonomic work that is so valuable, and becoming increasingly more so, to the economic entomologist. It is the first survey of its kind made in East Africa south of the Sahara, and it should enable entomologists and agricultural officers to recognize their species accurately.

The Colonial Office is to be congratulated on promoting this study, and it is to be hoped that it will be followed by similar surveys in other areas of Africa and elsewhere. If they are all as well and carefully executed as in the present instance they will mark an important advance.

W. J. HALL

PSYCHIATRY IN WARTIME

Psychiatry in the British Army in the Second World War

By Robert H. Ahrenfeldt. Pp. xv+312. (London: Routledge and Kegan Paul, Ltd., 1958.) 35*s*. net.

DR. AHRENFELDT fights once again the battles fought during the Second World War by British Army psychiatrists, "unwelcomed and regarded with suspicion, if not despised, . . . to overcome prejudices, administrative resistance and executive inertia, while simultaneously caring for their patients . . . " (p. 251). The brave partisan attitudes so frankly displayed in this passage pervade his book. They are not compatible with a discerning appraisal of the scientific, technical or administrative problems. Yet account should be taken of them by everyone who studies the history of Army psychiatry, or, for that matter, the development of civilian psychiatry in the years immediately following the War, because they appear to have been shared in some degree by several of his colleagues. Whether or not Dr. Ahrenfeldt wins the reader's sympathy, his book serves a useful purpose as a concise and accurate chronicle of the changes in official policies during the War years.

Let no one diminish the achievements of Army psychiatrists. A great deal was demanded of them. Equipped with the knowledge and skills acquired during their medical training and their specialist experience in hospitals and private consulting rooms, they were required to tackle not only the problems of organizing the treatment and disposal of psychiatric casualties, but also the multifarious problems of personnel and officer selection, training, discipline and morale and the management in Army units of the dull, unstable and delinquent. They had to be experts in matters lying outside their previous experience because there were no other experts. Many of the problems had been recognized in the First World War, and were noted in the report of the Southborough Committee in 1922, but the Army entered the Second

World War without any organization or trained staff to meet them. The Royal Navy and the Royal Air Force were perhaps more successful than was the Army in utilizing the services of civilians trained in the methods of social and applied psychology, and the psychiatrists in these Services dispersed their efforts less widely.

Many of the criticisms to which Dr. Ahrenfeldt makes reply appear to have arisen when the expertness of psychiatrists was called in question. For example, their participation in the selection of officers at War Office Selection Boards was controversial. A special position was claimed for the psychiatrist "as the only member of the Board with adequate scientific training and experience in the assessment of personality" (p. 66). Yet it could reasonably be doubted whether he was therewith fitted for the position claimed for him. The problems were new ones, and the immodest insistence by some psychiatrists of the superiority of their theories and techniques, in this and other matters, did damage to their reputation. However, in assessing the rights and wrongs of their claims, it should be remembered that the problems were important and urgent.

D. Russell Davis

PHONETICS

Manual of Phonetics

Edited by L. Kaiser. Pp. xv+460. (Amsterdam: North-Holland Publishing Company, 1957.) 38 guilders.

THIS book is divided into six parts, dealing respectively with the history of phonetics, the basal sciences of phonetics, phonetic research, phonetics in its relation to linguistics, phonetics in its relation to other sciences, and phonetics and the origin of speech. The twenty-eight chapters which make up these six parts have been contributed by thirty different authors (there are several collaborations), coming from fourteen different countries; they all write in English, sometimes in an English that is not very easy to follow. Curiously enough there is no contributor from Britain. The editor's introduction explains that the book is not addressed to a specialist audience, but is intended to provide a general introduction to the subject for such people as engineers, linguists, surgeons, psychologists, teachers, artists, and so on; and it is claimed that an all but complete survey of the field is provided. This, indeed, is what one would expect from a book entitled a 'manual'.

However, it is a disappointing compilation. It is certainly not a 'manual', in any sense, but is rather a collection of essays which have little unifying force behind them, and which are, moreover, of very varying worth. It does not provide anything like a complete survey of phonetics. The fundamentals of the subject are almost entirely missing: there is no detailed, systematic treatment anywhere of the basic categories of phonetic description, though such a treatment is needed for understanding many of the contributions; and there is no account of phonetic notation, apart from a few brief (and inaccurate) notes, at the beginning of the book, on the symbols used by the contributors (some of whom deviate unexpectedly from accepted practice). The languages taken into consideration fall very far short of being representative of the general range of human phonetic performance. It is disconcerting that some of the contributors do not appear to be phoneticians at all; one wonders what the collaborators who are phoneticians think of certain of the statements with which their contributions find themselves in company (such as one to the effect that "the average baby, under two months of age, is endowed with 7½ phonemes"). Several important techniques of phonetic research, including palatography and kymography, are referred to but nowhere explained. No mention is made of the uses of recording in phonetic investigation, and there is no discussion of methods of teaching pronunciation.

It is almost inevitable, in a work planned as this one appears to have been, that there should be no general body of theory common to all the contributors; it is scarcely surprising, therefore, that they contradict each other at times. More effort could have been made, however, to unify terminology: we find the same term used in two, and sometimes three, different senses by different writers (vocalization, accent, implosion, for example). What is more serious is that some terms are not explained anywhere in the book (for example, mixed vowel, lenis, fortis). A glossary of technical terms should have been provided. Even a carefully prepared index would have been a help; the present one is quite inadequate.

There are outstanding contributions by Peterson, Martinet, and Jakobson and Halle; but it is nevertheless not possible to recommend the book (quite apart from its price) to the layman who wants a manual of phonetics.

D. Abercrombie

SIR CHARLES SHERRINGTON

Sherrington

Physiologist, Philosopher and Poet. By the Rt. Hon. Lord Cohen of Birkenhead. (The Sherrington Lectures, 4.) Pp. xiv+108+3 plates. (Liverpool: Liverpool University Press, 1958.) 17*s.* 6*d.*

THIS volume is the fourth of the series of Sherrington Lectures instituted by the University of Liverpool in recognition of the distinguished contributions of the late Sir Charles Scott Sherrington to physiology and medicine, and of his association with the University as its George Holt professor of physiology during 1895–1913.

Lord Cohen has been the University's professor of medicine for a generation, and has chosen for his theme a much more personal subject than have the previous lecturers. He has also given reproductions of the Augustus John painting which hangs in the University Club of Liverpool, and of that by R. G. Eves which is in the Royal Society of London, as also of the photograph by Allan Chappelow which was chosen by Sherrington as the frontispiece to the second edition of "Man on his Nature", which was published on Sir Charles's ninety-fourth birthday. Apart from these three plates and a number of text figures, the book contains in its 108 pages a brief introduction, Lecture 1 which is biographical, Lecture 2 which deals with Sherrington as physiologist, and Lecture 3 which is of him as philosopher and poet. To these are added a bibliography, based on writings compiled for Denny-Brown's edition of "Selected Writings" and on John Fulton's obituary notice in the *Journal of Neurophysiology*.

Not so long ago it was a considerable labour and effort to piece together Sherrington's biography, but thanks to Prof. E. G. T. Liddell ("Obituary Notices of Fellows of the Royal Society", **8**, 241; 1952), Lord Adrian (*Proc. Roy. Soc. Med.*, **50**, 991; 1957), and others the effort has long since become less exacting, and opportunities for originality in Lord Cohen's Lecture 1 correspondingly less. One should, however, add the Beaumont Lecture given at Yale University on November 15, 1957, by "Sherrie's" son, Mr. C. E. R. Sherrington, for it is a noteworthy complement to other sources and is not too widely known.

Of his Lecture 2 Lord Cohen modestly wrote, "I have been able to touch only briefly and superficially on Sherrington's contributions to physiology. The work of a genius, who for half a century laboured with undiminished zest to unravel some of Nature's secrets, cannot be compressed, even in its essentials, into one lecture. It may well be that others would have chosen different examples from his work and a different emphasis to convey their assessment of his contribution to neurophysiology". Lord Cohen also refers to Sherrington's influence on the development of clinical neurology, where not only did he add, "as no-one had previously done, to the facts but above all he provided the concepts which made them hang together".

Lecture 3 is the most difficult to review, for it passes from physiology to the age-old problem of life and mind, posing difficulties at which Sir Charles did not baulk but which he recognized rather than solved. Then it completes the writer's would-be scope by referring to Sherrington's poetry and poetic thought, which make up a very interesting part of the full story, but need a poetic atmosphere for their proper discussion.

This review cannot give that, but perhaps enough has been said to reveal the scope of the lectures, and to whet the would-be reader's appetite for more. One cannot be too much in thought with Sherrington, or be too thankful that so wonderful a person lived in our time. We are in debt to Lord Cohen for his delightful tribute to so outstanding a member of the Liverpool faculty of an earlier day.

MISSILE ENGINEERING DESIGN

Missile Engineering Handbook

By C. W. Besserer. (Principles of Guided Missile Design, Vol. 4.) Pp. xi+600. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1958.) 109*s*.

Guided Missiles

Operations, Design and Theory. (Sponsored by the Department of the Air Force.) Pp. vi+575. (New York: McGraw-Hill Book Company, Inc.; London: McGraw-Hill Publishing Company, Ltd., 1958.) 62*s*.

The ever-increasing development of guided weapons for military purposes, research rockets for upper atmosphere measurements, and earth satellites and space probes implies a huge host of scientists, technicians and engineers working in the many disciplines of science and technology involved in these new devices. Despite the growing need for authoritative text-books on the associated wide range of applied science, it has, until recently, been difficult to find more than semi-popular expositions, liberally strewn with illustrations of war-time German missiles and American missiles at the instant of launch. The American series of admirably produced volumes on "Principles of Guided Missile Design", edited by a retired U.S. Navy captain for many years closely associated with missile development, and published by Van Nostrand, has gone far to rectify the situation.

This series began in 1955 and the fourth volume—"Missile Engineering Handbook"—is intended as a compendium of design data for use by engineers and technicians who may be assumed to have acquired a good knowledge of basic principles from the earlier volumes. It contains 400 pages of closely packed tables, graphs, nomograms and charts providing a remarkable accumulation of engineering data in the various subjects which make up the complex applied science of missile design. One may browse through specific gravity tables with such curious items as porphyry, hemlock or pine-yellow long-leaf, and speculate on their usefulness in the mundane business of fabricating anti-aircraft rockets, or pause to check the cumulative probability of meteor hits on journeys through space. In the intervals, however, can be found exhaustive tables of properties of materials, rocket propellant performance, the Earth's principal characteristics and gravitational field out to great heights and many other topics, together with most of the basic formulæ useful for design calculations. Much information is given of great value for preliminary design studies, divided into chapters on properties of the atmosphere, materials, aerodynamics, propulsion, avionics and space flight. The data on materials and structural design are particularly extensive. However, the sections on specifications for environmental tests and ground equipment and what seemed to be reminder lists for the process of detail design, all based on American practice, are of limited interest. The chapters on aerodynamics and avionics are rather brief. At the end is a 160-page glossary of terms commonly used in missile engineering, which should prove most valuable to newcomers in the subject. The layout and printing are extremely clear. There are, however, quite a number of misprints and some errors in basic constants, for example, the powers of π on p. 23 are completely inaccurate. These errors raise some doubts regarding the accuracy of the multitude of quantitative facts throughout the book, which only detailed and intensive study could check.

By contrast the second book, "Guided Missiles—Operations Design and Theory" deals almost entirely with elementary principles. It is based on a military training manual written some three years ago at the U.S. Air Force Missile School in Colorado and is obviously intended for general instruction of military personnel. Although at times unsound on basic principles, for example, force, momentum and weight are sadly confused in stating Newton's laws, the book gives a very understandable account of the main design principles and features of typical missile guidance and control components. The sections on systems are less successful, and there are noticeable gaps in the treatment of servo-mechanisms and closed-loop systems. The text is profusely illustrated throughout by exceptionally clear line and half-tone diagrams. The subject-matter should be easily grasped by a reader with mathematics and science to Intermediate B.Sc. standard and, despite a tendency towards diffuseness and occasional inaccuracy, forms a good introduction to all aspects of missile development.

Basic Automatic Control Theory

By Prof. Gordon J. Murphy. (The Van Nostrand Series in Electronics and Communications.) Pp. xi+557. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1957.) 9 dollars; 67*s.* 6*d.*

THIS book gives a detailed treatment for most of the basic theory pertinent to the analysis of linear feed-back control systems. The author deals first with Routh's criterion for stability, and with calculation of ultimate-state response. Techniques used in frequency response and time-response calculations are described. These include the *G*-plane (Nyquist) polar plot, the use of Bode gain-frequency diagrams, the root locus method for obtaining closed loop poles of the characteristic equation of a system from its open-loop poles, and the construction of the system time response from the closed-loop poles. Floyd's method for constructing impulse response from frequency response is also shown.

The introductory chapters, illustrated by a large number of very clear schematic and block diagrams, present various examples of control system components, and introduce the concept of transfer functions for each component part of a system. Block diagrams are built up for typical systems, and these are reduced to simple signal-flow diagrams. Laplace transform theory is also included among the introductory chapters, and the final chapter in the book gives a brief account of analogue computors and their use in simulation of feedback control systems. Certain parts of linear theory have been omitted, including the behaviour of linear systems with random input signals, and phase-plane analysis, but such omissions do not detract from the value of the book. Numerous worked examples are used throughout to illustrate the theory presented, and these examples are invaluable in providing a sound practical understanding of the subject. The book should prove useful to final-year and postgraduate students as well as to servo-design engineers, especially in respect to the excellent examples and unworked problems.

M. J. SOMERVILLE

Science in Schools

Proceedings of a Conference under the auspices of the British Association for the Advancement of Science, held on April 17th and 18th, 1958, at the Royal Geographical Society, London, S.W.7. Edited with Postscript by W. H. Perkins. Pp. viii+150. (London: Butterworths Scientific Publications, 1958.) 15*s.*

DURING April 17–18, 1958, the British Association for the Advancement of Science held a conference to focus attention on the condition of science teaching in schools. The subjects discussed included the national need, science as a component of general education, scientific education for girls, the present position of science teaching, the supply of science teachers and the role of the university and teachers' training colleges in providing them, accommodation and equipment and the part played by local education authorities in their provision. Among the speakers were Lord Heyworth, Sir Solly Zuckerman, Sir Eric James, Miss E. M. Huxstep, Dr. A. W. Barton, Dr. J. W. F. Hall, Dr. B. E. Lawrence and Lord Tedder. All the speeches and discussions have now been summarized in this book, which contains an introduction by Sir Alexander Fleck and a postscript by W. H. Perkins. The British Association and publishers are to be commended for presenting the proceedings of a nationally important conference in such attractive and readable form so quickly after the conference that the views presented are still fresh, lively and urgent.

Methods of Analytical Histology and Histo-Chemistry

By Edward Gurr. Pp. xv+327. (London: Leonard Hill (Books), Ltd., 1958.) 70*s.* net.

THIS is essentially a practical book designed for use at the laboratory bench, and, with this end in view, the techniques described have been set out very fully. The volume includes all the standard histochemical techniques, and often gives details of the several variants of any particular method. The difficult subject of protein histochemistry has been well covered; the very adequate instructions for the synthesis of some of the reagents used in, for example, the localization of sulphydryl groups by Barnett and Seligman's method are a welcome feature.

For the benefit of workers who do not have ready access to libraries, certain sections of the book are introduced by a theoretical passage which includes sufficient biochemical detail for a proper understanding of the different tests. The details of each reaction are followed by a selection of notes which point out possible sources of error, and these, together with a useful appendix containing such information as a list of buffer tables, of solubilities of various reagents and the formulæ of many dyes and staining solutions, add greatly to the value of the book, which may be readily commended to all who use histochemical methods.

S. BRADBURY

Curious Naturalists

By Dr. Niko Tinbergen. Pp. 280+54 photographs. (London: Country Life Limited, 1958.) 35*s.* net.

IN his introduction to this book, Niko Tinbergen describes it as the work of a small number of naturalists who, over a period of some twenty-five years, joined him in studying the behaviour of animals in their natural environment. He would be much too modest to say that most of the work described was initiated by him and continually inspired by his never-flagging enthusiasm. His friends throughout the world will greet his book with delight; many young naturalists will discover that the field of original investigation is still largely uncharted and awaits only the lively mind allied to a curiosity which is never stilled.

The book is cleverly written. In the opening chapter Tinbergen shows how, in the lovely country of Hulshorst in Holland, his first observations began in a somewhat diverting encounter with the digger wasp, *Philanthus*. From there the story is switched to East Greenland to the study of snow-buntings and phalaropes. Further investigation of *Philanthus* is followed by the study of the fast-flying falcon, the hobby. So the book continues with more studies of insects, birds and flowers, all serving to illumine contemporary knowledge of morphology, genetics and the mechanics of evolution.

The book is written in a narrative form which commands attention and is illustrated by superb photographs and quaint line-drawings which are always relevant to the text. "Curious Naturalists" should be much read.

THE GEOLOGICAL TIME-SCALE

By DR. K. I. MAYNE
Clarendon Laboratory, Oxford

AND

DR. R. St. J. LAMBERT and D. YORK
Department of Geology and Mineralogy, Oxford

THE sequence of geological events in many parts of the world since the pre-Cambrian has been well established by palæontological studies. The relative duration of each of the various periods into which it is customary to divide post-Cambrian time has also been estimated from a comparison of the maximum thickness of sediments laid down during each period. In order to use this relative scale as a time-scale, some geological events which are unambiguously placed in it, preferably within narrow limits, must be dated in an 'absolute' fashion. It is of course essential to make sure that one is dating the supposed event, and not some subsequent one. In this manner, Holmes[1] has proposed an absolute geological time-scale, his scale *B*, which places the Upper Cambrian at approximately 450 million years ago. Recently, we have undertaken an investigation of the ages of British igneous rocks by the argon – potassium method; and we have found discrepancies between the well-established stratigraphic assignment of our samples and the Holmes *B* time-scale. It appears that this scale is too short, and that the age of 450 m.y. given to the Upper Cambrian should be closer to 650 m.y. That the Holmes time-scale is too short has already been suggested by Ahrens[2] and by Faul[3], among others.

The 'absolute' age values on the Holmes scale are based upon seven uranium – lead ages determined by Nier[4]. Some of the specimens proved to have discordant age values, and those with ages which were concordant were of somewhat doubtful stratigraphic assignment. The discordancy had previously been thought to be the result of leakage of radon. For example, in the case of the Swedish Kolm, stratigraphically well defined in the Upper Cambrian, Nier's isotopic data for lead and uranium give age values for the ratio lead-207 to lead-206 of 800 m.y., for lead-207 to uranium-235 of 440 m.y. and lead-206 to uranium-238 of 377 m.y. Assuming loss of radon to be the primary cause of this discordance, Wickman[5] concluded that the absolute age of the Kolm is 440 m.y. It is thought that loss of radon is not significant except in the case of very young minerals[6]. Ahrens has suggested that the pattern of discordant ages found is due to loss of lead; and on this basis (with Nier's data) he has remarked that "slightly greater than 800 m.y. must be considered as a possible magnitude of the Upper Cambrian". More recently, Cobb and Kulp[7] have dated the Kolm, and although they find discordant lead-207/lead-206 ages as high as 720 m.y., they believe the true age to be no greater than 550 m.y. We are grateful to Prof. J. L. Kulp for informing us during the preparation of this communication that he now believes that his samples, and those of Nier's, may have been thermally altered by a basic sill occurring 100 m. above the Kolm. It would thus appear that so far the Swedish Kolm is open to criticism as a 'calibration point', for although its stratigraphy is well established, its age is still in doubt. On the other hand, the samarskite sample cited by Holmes, which is concordant in its age values, has an uncertain stratigraphic assignment, as indicated in Fig. 1. None of the samples used by Holmes is free of criticism on one or other of these grounds. Lead age data in many cases are not amenable to an unambiguous interpretation in order to give the true age. The argon – potassium method of dating may be able to provide more precise ages for fixing known stratigraphic horizons in the absolute time-scale; and particularly so when it is corroborated by the rubidium – strontium method.

The ages of the coarse-grained British granitic rocks have been determined by us on separated biotite (which is assumed to have complete retention of its radiogenic argon) by the argon – potassium method. An account of our analytical procedure and the detailed geological description of our samples will be published elsewhere. Argon was extracted from the mineral by heating to 1,500° C. in an induction furnace, and measured both volumetrically, and by the isotope dilution technique, using argon-36 as a tracer; there was agreement by both methods

Table 1

Sample	Stratigraphic position	Mineral	Method	Age (m.y.)	Ref.
A, Chinle Formation, Colorado Plateau	Upper Trias	Pitchblende	U–Pb	[a]200–210	14
D, Beryl Mt. Pegmatite, N.H.	[b]Upper Devonian–Carboniferous	Muscovite	A–K	324	12, 19
F, Franco–German Hercynian	Upper Dinantian or Namurian	Biotite	A–K and Sr–Rb	345	3
G, Georgia Piedmont	Permo-Carboniferous	Micas	A–K and Sr–Rb	360	13
O, Bentonite, Chattanooga Shale	Upper Devonian	Biotite	Sr–Rb	414 ± 45	15
P, Givetian of Saskatchewan	Middle Devonian	Sylvite	A–K	425	17
H, Bear River, Nova Scotia	Post-Lower Devonian	Biotite	Sr–Rb A–K	370 365	8
M, Nictaux Falls, Nova Scotia	Post-Lower Devonian	Biotite	Sr–Rb	391 410	8
T, Boisdale Hills, Nova Scotia	[c]Post-Lower Devonian	Felspar Biotite	Sr–Rb	486	8
I, L. Dubuque Formation, Minnesota	Upper-Middle Ordovician	Felspar	A–K	390	10
R, Bentonite, Stone Rivers Group, etc.	Middle Ordovician	Biotite	Sr–Rb	451–496 ± 50	15
B, Dartmoor granite	Post-L. Westphalian, pre-L. or M. Permian	Biotite	A–K	305	Ox.
C, Oslo Alkali Suite	Stephanian or L. Permian	Biotite	A–K	308	Ox.
E, Land's End granite	Post-L. Westphalian, pre-L. or M. Permian	Biotite	A–K	340	Ox.
S, Cairnsmore of Fleet granodiorite	Post-Silurian, pre-L. Carb.	Biotite	A–K	470	Ox.
U, Shap adamellite	Post-Silurian, pre-L. Carb.	Biotite	A–K	475–510	Ox.
N, Mynydd Mawr microgranite	Lower–Upper Ordovician	Felspar	A–K	410	Ox.
		(70 per cent retention		550)	Ox.

(*a*) This may not represent the age of the formation in which the pitchblende is found; (*b*) the stratigraphy is probably less precise than this (Kulp, private communication); (*c*) see ref. 8 for an alternative stratigraphy.

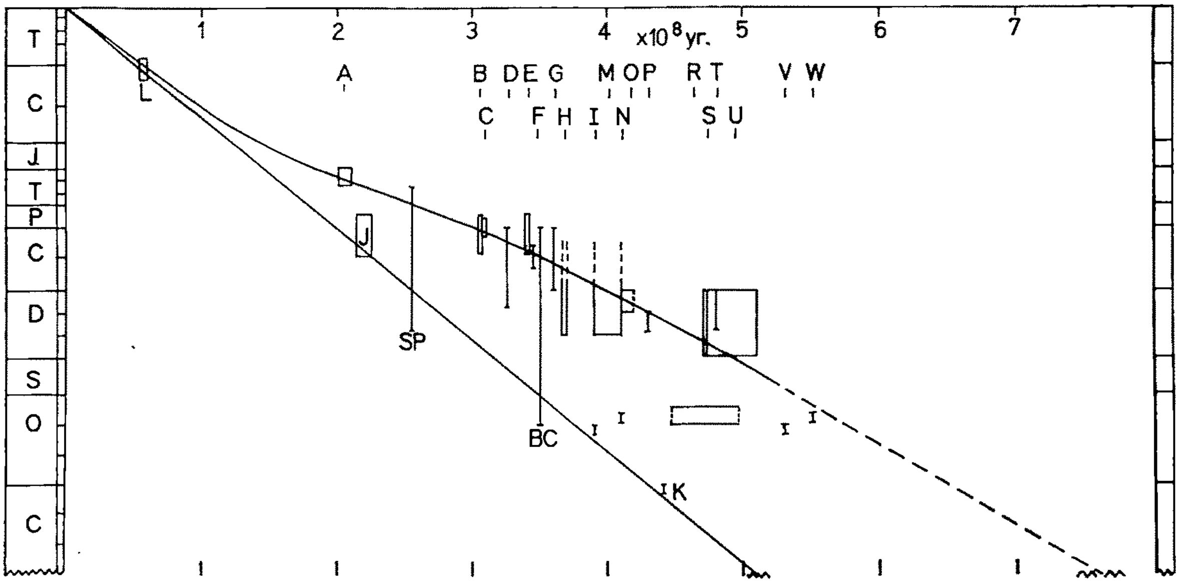

Fig. 1. Graph showing measured ages plotted against the stratigraphic column

Key. Holmes scale (on curves): *L* = Laramide orogeny; *J* = Joachimstal pitchblende; *SP* = Spinelli samarskite; *BC* = Bedford cyrtolite; *K* = Kolm

Other determinations:

A Chinle formation
B Dartmoor granite
C Oslo alkali suite
D Beryl Mountain pegmatite
E Land's End granite
F Franco–German Hercynian
G Georgia Piedmont
H Bear River, Nova Scotia
I Dubuque formation
M Nictaux Falls
N Mynydd Mawr microgranite
O Devonian bentonite
P Givetian of Saskatchewan
R Ordovician bentonite
S Cairnsmore of Fleet granodiorite
T Boisdale Hills, Nova Scotia
U Shap adamellite
V Dubuque formation, 70 per cent retention
W Mynydd Mawr, 70 per cent retention

All Oxford values estimated as ± 5 per cent, constants used being $\lambda_\beta = 0{\cdot}476 \times 10^{-9}$ yr.$^{-1}$; $R = 0{\cdot}123$.

The relative lengths of the geological systems are taken from the Holmes scale; the younger end of the curve is drawn to agree with data reported by Evernden (private communication).

within a few per cent. The reliability of the apparatus was checked by measuring the ages of previously determined samples obtained from the Department of Terrestrial Magnetism and by determining the argon content of atmospheric air. The atmospheric argon contamination and other possible impurities of the samples were checked mass spectrometrically. The precision and reproducibility of argon determination was better than 2 per cent. The potassium content was determined by flame photometry to approximately 2 per cent.

The results of our age determinations are given in Table 1. These samples have been chosen chiefly because their positions in the stratigraphic column are well defined. (We have found that other British granitic rocks belonging to the same petrographic provinces, but of doubtful individual stratigraphic assignment, give consistent results.) This has allowed us to draw the curve shown in Fig. 1, relating the geological age to the absolute age. In the past it has been customary in many cases to re-interpret any rather doubtful stratigraphy of samples measured, in order to fit them to the Holmes scale. Our results show a systematic divergence from this Holmes scale. In Table 1 we also give a number of published ages of samples for which the stratigraphy is less precise, in order to show their relation to our curve.

It is now seen that Faul's Hercynian ages, derived mainly from rubidium – strontium data, are compatible with the Dinantian–Namurian stages of the Carboniferous. The age values for Bear River and Nictaux Falls[8] would place these in the Devonian; field-evidence indicates that these granites intrude into lower Devonian[9], and so cannot be Ordovician as would be indicated by the Holmes scale. On our time-scale, the Boisdale granite was intruded into the early part of the Devonian.

Our age value of 410 m.y. for the Mynydd Mawr microgranite, which has been assigned to the Caradocian stage of the Ordovician, is to be compared with the measurements of Wasserburg and Hayden[10] on the upper-Mid-Ordovician Dubuque felspar. They dated this at 495 m.y.; which would be reduced to 390 m.y. if one uses the presently accepted nuclear constants in calculating the age. However, felspars are observed to have lost about 30 per cent of their radiogenic argon during their life-time[11], and allowing for this leakage both the Mynydd Mawr and Dubuque samples lie close to the new scale.

Damon and Kulp[19] have estimated the age of the Beryl Mountain formation, which is Upper-Devonian–Carboniferous[12], to be about 325 m.y., which agrees with the new scale. Measurements by Kulp and Long[13] of the metamorphic and igneous rocks of the Piedmont, using argon – potassium, rubidium – strontium and uranium – lead ratios, give an age value of 360 m.y. These were probably formed during the Permo-Carboniferous Appalachian orogeny, which places them on the new curve. Miller and Kulp[14] have reported that uranium – lead ratios of the Upper Triassic Chinle of the Colorado Plateau indicate an age of about 210 m.y.—once again higher than the Holmes Upper Triassic.

The recent measurements by Adams *et al.*[15] on an Upper Devonian bentonite lend further support to an extended scale. The value of approximately 410 ± 40 m.y. found from rubidium – strontium measurements is considerably higher than that which would be inferred from the Holmes scale; but it would fit well on the new scale. Two Middle Ordovician dates which they report fall roughly midway between the two scales.

The extended time-scale also has a bearing on the reported values of the diffusion coefficient of argon in sylvites of known stratigraphic age. The work of Gentner and his collaborators[16] on Oligocene sylvites from Büggingen and Alsace indicates a value of $D = 1\cdot5 \times 10^{-19}$ cm.^{2}/sec. at 40° C. This value has been criticized in detail by Folinsbee, Lipson and Reynolds[17] and Curtis and Reynolds[18], on the basis of measurements on an upper Middle Devonian (Givetian) sylvite. This sample had an apparent age of 285 m.y. from its argon-40 and potassium-40 content, while its true age was taken as 325 m.y. on the basis of the Holmes scale. Its deficiency in argon-40 was then explained by assuming loss by diffusion, with $D = 3 \times 10^{-20}$ cm.^{2}/sec. However, using the Gentner value for D gives an age of 430 m.y. for this salt, placing it correctly in the Devonian in our scale.

An extension of the Holmes time-scale appears necessary to explain the results given here. Unfortunately, intrusive granitic rocks cannot be placed within narrow limits in the stratigraphic column; hence the large spread in the ordinate values of the plots on Fig. 1. It may be that the relative extent of any particular system in the column is in error, so that a good fit to a straight line is not to be expected. The method of estimating maximum thicknesses of sediments, especially in the earlier stages, is open to question. In this connexion it would be particularly desirable to have some unambiguous dates in the Ordovician and Cambrian. To define the extent of any system in detail it is clearly necessary to have the ages of materials, as, for example, lava flows, known to be from the beginning and end of the system. We do not consider that the biotites have inherited argon. Faul's rubidium – strontium ages were in agreement with his argon – potassium dates. The granitic rocks we have dated come from widely varying geological environments with differing contents of potassium, history and petrogenesis. Furthermore, Damon and Kulp[19] conclude from measurements on calcium micas that primary argon is not a significant source of error in the argon – potassium method of dating.

Some evidence has been brought forward in support of Holmes's scale, notably by Gentner and Kley[20], who gave figures for felspars from the Hercynian of south-west Germany; and also by several workers who have analysed glauconites (for example, Wasserburg *et al.*[10] and the group working on the subject at the Massachusetts Institute of Technology[21]). Gentner and Kley's results ranged from 306 m.y. to 237 m.y. for the intrusive rocks of the Hercynian orogeny, which, assuming no loss of argon, agree with the Holmes scale for the Lower Devonian to the Lower Carboniferous. We have, however, found that felspars retain only 70–90 per cent of their radiogenic argon in this age-range; and if such a percentage loss occurs in the German samples, they would be compatible with our scale. The suitability of glauconite as a mineral for the determination of age has yet to be proved, as glauconite is a very variable mineral species, usually extremely fine grained, of unknown genesis and easily subject to subsequent recrystallization.

We are grateful to Mr. C. McInnes for carrying out much of the experimental work. This project forms part of the programme on geological age and isotopes at present being carried out in the Department of Geology and Mineralogy, Oxford.

Note added in proof. Prof. J. L. Kulp now informs us that measurements made on Kolm material taken several miles from the sill, and hence not thermally altered by it, show a discordancy similar to that previously found (to be published shortly); and loss of radon by diffusion may account for some of this discordancy.

MARL: AN ANCIENT MANURE

By G. E. FUSSELL

ARTHUR YOUNG eulogized the custom of marling in 1769 in the following words: "All the country from Holkham to Houghton was a wild sheep walk before the spirit of improvement seized the inhabitants. . . . What has wrought these vast improvements is the marling; for under the whole country runs veins of a very rich soapy kind, which they dig up and spread upon the old sheep walks, and then by enclosing they throw their farms into a regular course of crops and gain immensely by the improvement"[1].

The process was well established when Young wrote the passage, and, according to his preface, had been initiated by Lord Townshend and Mr. J. Allen a good many years before. He made what might have been a more permanent record of this on his wife's tomb in Bradfield Combust church. Her obituary there states that she was the great-great-granddaughter of John Allen, Esq., of Lyng House in the county of Norfolk, the first person, according to the Comte de Boulainvilliers, who there used marl[2]. Only one farmer on the similar light land between Stoke and Thetford in Suffolk had bothered to use this method of improving his land in 1769. Much of the land in this area was then quite uncultivated, which surprised Young, because marl was to be found in many places beneath the sand[3].

The "Six Weeks Tour" was the first of Young's farming journeys, and was only incidentally concerned with agriculture. At that time he was inexperienced. He really knew little about the subject in which he was to achieve such great authority, and marling was new to him. He makes it clear that this method of reclaiming light land in part of Norfolk had been practised for some decades; but he does not give any explanation why John Allen first, and then Lord Townshend, should have begun to dig and spread marl if they, in fact, did initiate the process in that area. It may indeed have been something new there towards the end of the seventeenth century. More evidence is necessary to certify this, but it is quite certain that marl was used in other parts of the kingdom, and had been from at least the sixteenth century, and, possibly with some intermissions, from before the Roman occupation.

The word 'marl' has been used embracing a miscellany of earths dug out of the subsoil and spread upon the surface to increase fertility. Some of these subsoils have performed the function, notably clay spread on the fenland, but were not marl. Some typical marls, mixtures of chalk and clay, are derived from argillaceous limestones, such as some beds of Lias and Keuper. Marl containing carbonate of lime is far more valuable as a fertilizer than clay; it improves soil texture, adds carbonate of lime, potash compounds and sometimes phosphoric acid. Many light and blowing sands, like those that Young reported upon, have a bed of marl or clay near or beneath them, which can be readily obtained[4]. It is composed of a mixture of calcareous and other material in very varied proportions. Its precise definition is accordingly difficult.

The virtue of the material is said to have been recognized by the prehistoric Greeks, notably in Aegina, "where their use became a theme of mythology". Mineral fertilizers were found in their native states, either as earths like marl, or as deposits of alkaline salts like carbonate of lime, or nitrate of potassium (nitre), and mixing earths was first advocated by Theophrastus, according to Mrs. Semple. (She gives a modern interpretation, for I understand the Greek chemists did not know nitre.) It had the results set out by Sir Daniel Hall three millennia later. The Aegina surface stratum was a poor freshwater limestone underlaid by a stratum of fertile marl, which was dug out and laid on the surface to form a soil. The same thing was done in nearby Megara. Again, marl was a component of Tertiary Terraces[5].

Pliny, who disliked soil mixing, that is, sand on clay or clay on sand, confirms the use of marl in Megara, a marl-like white clay, and mentioned the different sorts by colour used in Britain and Gaul. They were the white, red, dove-coloured, etc. These were of two different qualities, acrid and fat. The white, often dug from deep pits, was that chiefly used in Britain. He made a distinction between that suitable for corn and for fodder crops, and estimated a rather exaggerated benefit lasting as long as eighty years. There was, however, no marl in Italy, and the Romans knew nothing of its use by experience. Varro, too, remarked the use of marl, a white fossil clay, as a fertilizer in Transalpine Gaul—*ubi agros stercorarent candida fossicia creta*—which Mr. Storr-Best had no doubt was the *Marne*, a natural mixture of lime and clay still used in France in 1912, and identical with the material used by the Greeks. Columella's uncle used it on his farm near Cordova, in Spain[6].

Between the fall of Rome and the thirteenth century there is a gap in the evidence. Whether marl continued to be dug and used in England during the centuries between is not known to me: but it is probable that it was used in France, and especially in Flanders. Oddly, it was on the clay lands there that marl was spread regularly and with excellent effect, because wet clay easily becomes sour, especially when the surface is little disturbed as in cereal growing. It was therefore necessary every few years to bring a heavy calcium concentration to these soils to neutralize the acidity. This was achieved by marling, which Lindemans justly describes as a remarkable piece of agricultural empiricism by a people who possessed no inkling of modern chemistry, but is quite contrary to the later English jingle:

He who marls sand
May buy the land;
He that marls moss
Suffers no loss;
He that marls clay
Throws all away.

In the Belgian sand land there is no early mention of marling, but the Flemish clay lands frequently have field names including marl and pits from which marl could have been dug before the end of the Middle Ages. Tenants in the area between Leuwen and Haspengouw were obliged by their leases to spread marl every so often, and the obligation continued. In other places marl was a complement, but not a substitute, for stall manure. The use of the material may have declined here with the increased production of stall manure, which it influenced indirectly by affording better yields of straw and fodder crops, but tenants who had insufficient dung were required by their leases to use it until the seventeenth and even the eighteenth century[7].

The open fields in Great Britain contained many disused marl pits in the early sixteenth century[8], and these may have been some centuries old. Walter of Henley was a protagonist of the manure in the thirteenth century. He thought the effects of marl lasted longer than that of manure, and indeed of earth and manure mixed, which was better than the simple dung. He advised spreading marl on the ground of the sheep fold every fortnight, and the anonymous "Seneschaucie", of about the same date, required the bailiff to "cause the land to be marled, folded, manured . . . as his knowledge may approve". The wagoner, too, ought to know how many times in the day the horses could go to carry marl or manure to the fields; some of this was repeated in "Fleta"[9]. These books can only be accepted as reflexions of the best practice of their day. They can scarcely have been speculative or imaginative works like those of so many of the later book-farmers, though it is possible they owed something to classical writings. Consequently, some medieval farmers in England were acquainted with the use of marl, and their use of the material was the cause of the disused marl pits noticed by Fitzherbert. He, too, was doubtless well read in such versions of the classical authors as were then available, and his ideas influenced by them. This must have been a pertinent reason why he deplored the stupidity of some early sixteenth-century farmers who neglected marl.

There was what seemed to them a sound economic reason for their action. They would not improve their land by this or any other process because they feared their landlords would demand higher rents immediately higher yields were gained. This was rather a silly line of reasoning; but no doubt it seemed prudent to them. Fitzherbert was convinced that marling well done would last for twenty years[10].

No doubt Fitzherbert had travelled through parts of England, and was well equipped to make accurate agricultural observations on what he saw. His statement that few open arable fields were then manured with marl is by so much to be accepted, but when Leland was in Shropshire, Cheshire and Lancashire, he found marl was used for ameliorating the poor sandy soils in those three counties, and he names specific places where the results were good[11]. Since these were counties where the convertible husbandry was practised in some places, that is, grass was ploughed for a few years cropping and then returned to ley, marling may have been continued from old times, or only been intermittently interrupted. It was certainly usual, not only in these three counties, but also in Somerset, Middlesex, Sussex and Surrey by the end of the sixteenth century[12], and this leads to the conclusion that it may have been habitual, almost traditional, in these areas.

Gervase Markham, writing in the first quarter of the seventeenth century, was a real enthusiast for marl. He recalled Pliny's statement that the Britons used it, and that it was mentioned in books of gainage or husbandry written in the reign of Edward II as well as by Walter of Henley. Markham himself describes how it was used by Kentish farmers when bringing areas of wealden land into cultivation. The quantity of marl used varied widely on different soils —as was wise. Marl was not, he said, good on clay land. On sandy or hazelly land 500 cartloads, containing 10 or 12 bushels each, could be usefully spread. The Kentish acre was 160 rods of 16 ft. After applying the marl, this land might be ploughed up and wheat sown, but some farmers broke up the grassland and took a crop of oats as was sometimes done during the recent war-time ploughing-up campaign. After this they spread the marl and sowed wheat. Land treated in this way must not be harrowed down fine. Only one or two crops were taken, and then it was let fall down to grass for five or six years. Markham rather optimistically said that "all this time it will beare a very good and sweet Pasture, well set with a white Clover, or, three leav'd grasse, most fatning and profitable, both for Sheepe and Bullocks". When the appropriate time had passed the ley was broken up again for two or three years crops. Under this system the effects of marling could be enjoyed for some thirty years, but if too many crops were taken it would be exhausted in five years. Was this the system employed elsewhere in the country where marl had continued to be used ? Very probably it was.

Four sorts of marl were found in the Weald, distinguished by their colour, grey, blue, yellow and red. Their order of merit was blue, yellow, grey, red. All were good material if as slippery as soap[13].

Whether marl continued to be used in France from the time when the practice was first observed by Cæsar's soldiers or not is difficult to say, but it seems probable. When Estienne and Liebault wrote their "Maison Rustique" in the sixteenth century they spoke of manure as either rotten dung or marl, and advised that the dung or marl be spread in the increase of the moon about November 18. Bernard Palissy, too, whose knowledge of soils was acquired during his researches into the best kind of clay for making pottery, included in his "Discours admirables" a chapter on marl, its value, how to recognize and where to find it. The familiarity with which these and other French writers deal with the use of marl suggests that it was generally used by French farmers when they were fortunate enough to find it[14].

Throughout the seventeenth century the English didactic writers continued to advise the use of marl, and the best way of doing so. Hartlib recorded that the men of Essex called the scourings of their ditches marl in the same way as pond mud was called 'Marle de mare' in a Waalse lease. Blith was sufficiently interested to carry out what must surely be one of the first comparative experiments in fertilizers. He used marl, pond mud, dung, and folk mucked two or three lands with each, and even had a control plot untreated. Of course he did not record the resulting yields arithmetically, but found the marl compared favourably with the other treatments, and fertilized nine years crops[15]. When the nascent Royal Society made its Georgical inquiry just after the Restoration it included in its questionnaire an exhaustive demand for information about the availability of marl, its depth, colour, the soils upon which it was used, and in what quantity, what time of year it was applied, and the crops which succeeded best on the land treated. How long its effect lasted was also asked, a question answered very variously from classical times onwards, but in his examination of the surviving returns Mr. Lennard does not say whether these questions were answered by any of the Society's correspondents. Unfortunately the Society was unable to secure a complete set of replies; but those that remain show that marl was then used in widely separated parts of Britain. In the Liberty of Ripon "Clay, Moorish and cold weeping grounds" were marled when broken for arable at 240 Winchester bushels the statute acre. Less was applied in other parts of Yorkshire, for example, in the Holme Beacon district. Marl was used in Devon and Cornwall as well as sea sand full of calcareous shells. Very heavy dressings were given in the "marl district" of Devon. Meadow land was marled in Wharfedale[16]. Evelyn had no doubt that relenting chalks or chalk-marl was a profitable fertilizer, and John Clayton informed the Royal Society that the tobacco growers of Virginia used only cow dung, although he had observed both red and blue marl at some breaks in the hills. In France, too, Louis Liger was a strong protagonist of marl, which was the best manure. Heavy dressings of 1,000–1,200 *voies* per arpent were given. The work was done in June or November, and, as elsewhere, the marl was left lying on the surface during the following winter so that it might be crumbled by sun, rain, snow and frost[17].

Even in Norfolk marling was being extensively practised by 1706, and had been on the Raynham Estate throughout the late seventeenth century. In 1731, at Holkham, 2,096 loads of marl were spread. Miss Naomi Riches supplies an ingenious explanation of the reason why it has been so often said that marling was abandoned from time to time and rediscovered[18]. The effects of the heavy dressings of marl were said to last for generations, from twenty to fifty, or eighty and a hundred years. Whether they did so is another question ; but the result of the long intervals that elapsed after a dressing of marl had been spread was that the new generation of farmers always regarded the process as one practised by its forefathers, and not presently current. Marling had therefore to be constantly revived. This is perhaps the explanation why it seemed so new and remarkable to Arthur Young, and that he and the Comte de Boulainvilliers thought it had been revived by Mrs. Young's great-great-grandfather, Mr. Allen.

On the Continent marl does not seem to have been subject to these intermissions. In Flanders it was superseded by the careful conservation of increased supplies of stall manure and animal urine plus town sewage and industrial waste, like rape cake. The reclamation of sandy lands was continued well into the nineteenth century, and was achieved by breaking through the iron pan beneath the sand, digging out the subsoil, stated to be "a stratum of loam", and spreading it upon the surface[19]. There was probably a mixture of calcareous material in this loam, but whether it was what we should call marl or not, I do not know.

The later history of the use of marl in England can be compressed into a paragraph. Throughout the eighteenth century the material was highly commended and extensively used at least by some farmers in many parts of the country. Change began with the introduction of bone manure, which soon began to supersede marl in Cheshire and the West Midlands. Early in the nineteenth century farmers were filling in the old marl pits and levelling the ground to increase the surface area of their farms. This was the beginning. The coming of manufactured and imported mineral fertilizers in the mid-nineteenth century did away with the need for the heavy labour involved in digging, carting and spreading marl, and the practice was abandoned once more, probably finally.

SCIENCE AND TECHNOLOGY IN THE UNIVERSITY OF BRISTOL

OPENING OF QUEEN'S BUILDING

ON December 5, H.M. the Queen opened and named Queen's Building, which is to house the four Departments of Engineering, Civil, Mechanical, Electrical and Aeronautical, together with the Departments of Geology, Mathematics and Theoretical Mechanics in the University of Bristol.

Though the number of students concerned has been relatively small, the teaching of engineering and applied science in the University of Bristol has always been strong. Even before the days of University College, such men as William Smith, a founder of modern geology, John McAdam, the father of English roads, and Isambard Kingdom Brunel worked long in the district and influenced the rising generation towards careers in engineering. As a result, when University College was opened in 1876 it attracted to its staff young engineers and scientists of unusual calibre. Hele-Shaw and Stanton, both appointed before 1900, later became national figures in engineering, and the latter, as Sir Thomas Stanton, created the Engineering Division of the National Physical Laboratory. Silvanus P. Thompson, appointed for both "physics and electrotechnics", became a leader both in engineering education in London and in electrical engineering. W. J. Sollas, later translated to Trinity College, Dublin, and then to Oxford, was an outstanding geologist of international reputation. Between the World Wars there were among the engineering professors, Andrew Robertson and A. J. S. Pippard, both happily still very active. To this period belong also S. H. Reynolds and A. E. Trueman, who brought to geology a width of outlook and depth of local knowledge that made Bristol with its natural local advantages for geological field-work a well-known centre for the study of geology. In these inter-war years, also, the late H. R. Hassé, who was distinguished for his work in relativity theory and molecular physics, built up the Department of Mathematics from its early beginnings.

When Bristol received its charter in 1910, the Engineering Department of University College and the senior staff of the Technical College which had been maintained for many years by the Society of Merchant Venturers were brought together to form the Faculty of Engineering. It was housed in the buildings of the Technical College in Unity Street and was presided over, first by Dr. Wertheimer, and later by Prof. Andrew Robertson, as principal of the Merchant Venturers' College and dean of the Faculty of Engineering in the University. This arrangement was a source of strength to the Engineering Departments of the young University, but as time went on it was found unsatisfactory for the staff to attempt to cover the teaching of technicians and university students; also the laboratory space available was cramped and unsuitable for university work, with its increasing emphasis on research. While the University staff was freed from teaching in the Technical College in the years between the Wars,

Fig. 1. Queen's Building, University of Bristol

and in the same period much first-class engineering research was produced, it is a matter for congratulation that the University, after forty years of invaluable help from the Society of Merchant Venturers, now has its Faculty of Engineering housed in the midst of the other University departments on an incomparable site, and in a building which gives the staff all the facilities they could desire for both teaching and research. The number of undergraduates now reading technology in Bristol is just under 350. It is to be hoped that with the opportunities now available the number will grow rapidly.

Queen's Building (see Fig. 1) stands on the southern brow of St. Michael's Hill just below the H. H. Wills Physics Laboratories. It has a commanding view over the city and docks of Bristol to the Somerset hills beyond. Construction was started almost nine years ago, and so goes back to the difficult days when labour and materials were in short supply. There is little to indicate this, apart from the fact that the framework of the building is of reinforced concrete, which gives a heaviness to many of the interior vistas. Some will find this pleasing, but it is a little out of keeping with the spirit of structural research in aeronautical and other fields, which has been during the past three decades, and still is, such a feature of Bristol engineering. The structure is lightened where possible by metal partitions and floor openings dictated by the specialist needs of the various departments. It was appropriate that in 1949 the first sod should be cut, incidentally using a mechanical excavator, by Prof. Andrew Robertson, at that time the dean of the Faculty of Engineering. It is very largely due to his outstanding work for the University over a period of thirty years, to his zeal and planning ability that the building exists to-day. With him was the architect, Sir George Oatley, senior partner of the Bristol firm of Oatley and Brentnall, which had been responsible for many Bristol buildings, including the University Tower and Library. Upon Oatley's death shortly afterwards, all the burden of architectural work fell upon his partner, Mr. Ralph H. Brentnall. Two Bristol contractors, John Perkins and Son and William Cowlin and Son, were responsible for the construction, the first for the preparatory work on the site and the second for the superstructure.

As will be seen from the accompanying photograph (Fig. 1), the building consists essentially of a large structure around an elongated courtyard, with two wings running from it east and west. It was the west wing and the western half of the central block that were constructed first. As soon as the foundation works for these had reached the centre of the building, the foundation stone to be seen beside the main entrance was laid on December 14, 1951, by Sir Winston Churchill, chancellor of the University, and at that time Prime Minister. The westerly parts of the building were completed in 1954 and at once taken into use, while work proceeded on the remainder of the central structure and on the east wing. At the same time, the Library building set on the hillside immediately before the southern front of the central structure was begun. It was finished in 1957 and the remainder of the work in 1958.

The building is approached by way of University Walk, with the gardens of the Royal Fort on the left and the Baptist College on the right. The main entrance leads directly to a spacious entrance foyer, in which will be noticed a plaque recording the special connexion between the Society of Merchant Venturers and the Faculty of Engineering. Like the walls around the entrance foyer, it is of gris mouchette, a marble-like limestone from northern France. The exterior is faced with a light-coloured brick from Cheshire with the principal features in Bath stone. Of the three main floors in the building, the lower ground floor is devoted to engineering laboratories: mechanical engineering in the west wing, aeronautical engineering in the east wing and civil engineering in the centre, with an additional laboratory under the Library. The ground floor, on the level of the main entrance, houses electrical engineering in the west wing and part of the centre, and the Department of Geology in the east wing. From the lower floors there is access to the Library which, with its gallery above, and stack room below, houses some 10,000 volumes and is designed to accommodate many more. On the first floor, lecture theatres and staff rooms occupy the centre block, with drawing offices, lecture rooms and tutorial rooms in the wings. At this level, also, the Departments of Mathematics and of Theoretical Mechanics are housed; the former, which serves the University as a whole, occupies much of the lecture room accommodation in the east wing, and the latter, which works primarily with the engineering departments, uses rooms in the west wing.

Further staff rooms are provided in a second floor which extends along the middle part of the building. Here also are some of the rooms set apart for postgraduate students.

It will be seen that the building gives all the departments within it new opportunities for extending or improving their equipment for both teaching and research purposes. In the field of civil engineering, the range of apparatus for the strength-testing of structures has been extended, and provision made for dynamic as well as static testing; and facilities for work on hydraulics and soil mechanics have been much improved. Better workshops, extended facilities for material and fatigue testing, and provision for the testing of gas turbines have become possible in the new mechanical engineering laboratories. The electrical engineering laboratories, in addition to extended testing equipment for general purposes, now provide several specially designed generator sets, which are the basic tools needed for research into problems in dynamo-electric machinery. The Department of Aeronautical Engineering, which owes much to the generosity of the Bristol Aeroplane Company in founding the Sir George White chair of aeronautical engineering some years ago, has several low-speed wind tunnels in operation, and more are planned. Compressors and a large high-pressure air reservoir are installed to provide for the operation of transonic and supersonic wind-tunnels. The Department of Geology has now adequate space for the display of its extensive collection of geological specimens, and has extended its laboratory work generally. All the Departments have been able, in addition to their teaching laboratories, to set aside proper space for research work.

There is no doubt that the provision of Queen's Building should enable Bristol to make an even greater contribution than it has in the past to the highly important field of technology and applied science.

J. F. BAKER

OBITUARIES

Prof. E. J. Maskell, F.R.S.

By the death of Ernest John Maskell on December 20 plant physiology in Britain has lost one of its most distinguished exponents.

Born in Cambridge on February 1, 1895, Maskell was educated at Cambridge County High School and the University of Cambridge, where he was a member of Emmanuel College. He graduated in 1919. With the award of the Frank Smart Studentship in 1920 he undertook research in plant physiology under the late F. F. Blackman. The results of this work on the diurnal rhythm of photosynthesis in leaves of cherry laurel in relation to carbon dioxide concentration, and on rates of photosynthesis in relation to stomatal opening, were afterwards published in the *Proceedings of the Royal Society*. After an appointment in 1922 to the Horticultural Research Station at Cambridge and a period at Rothamsted Experimental Station (1924–26), Maskell was appointed as plant physiologist at the Cotton Research Station in Trinidad. It was here, during 1926–30, that in conjunction with T. G. Mason he carried out the work by which he is best known and by which he is likely to be chiefly remembered, on translocation of carbohydrates, nitrogenous substances and phosphorus, potassium and calcium compounds in the cotton plant.

By 1930 Maskell's outstanding quality as an experimental plant physiologist was well realized and he was recalled to Cambridge to take up a lectureship, which was later raised to the post of reader in plant physiology. Here in the Cambridge Botany School for twenty-one years he was an inspiration to the many research students from Britain and overseas who had the advantage of his direction and supervision.

In 1951 Maskell was appointed to succeed me in the Mason chair of botany in the University of Birmingham. Just before his death he had been engaged in the troublesome task of developing plans for a new Botanical Department of the University.

Maskell was elected a Fellow of the Royal Society in 1939 and served on the Council of the Society during 1951–53. He was a member of the Agricultural Research Council during 1952–57 and represented the University of Birmingham on the governing body of Studley College from 1951 until his death. He was also a member of the governing body of the Grassland Research Institute, Hurley, a member of the executive committee of East Malling Research Station, of the Scientific Advisory Committee of the Empire Cotton Growing Corporation, and of the Advisory Panel of the Indian Tea Research Association.

Maskell was a life-long and active member of the Society of Friends and during the First World War served with a Friends Ambulance Unit. He was the most upright and kindest of men and those who had the privilege of his friendship held him in the highest regard. He married in 1923 Elisabeth Rose McCormick, who survives him. WALTER STILES

Prof. N. J. Scorgie

PROF. N. J. SCORGIE, Courtauld professor of animal husbandry in the Royal Veterinary College, London, died suddenly in his fiftieth year on February 10, 1958, in Iran, where at the instigation of the Food and Agriculture Organization of the United Nations he was conducting a mission related to re-organization and development of animal husbandry services. Jack Scorgie, as he was commonly known, was a 1929 arts and 1931 science graduate of Aberdeen, after which he took his veterinary diploma at the Royal Veterinary College and then joined the staff of that Institute. Following preliminary work in the Pathology Department and in preventive medicine, he transferred to the Department of Animal Husbandry, where he worked under Prof. W. C. Miller, whom he succeeded in 1946.

Scorgie had made the most of his wide training and was beginning to reap the benefit of his labours in organizing his Department, partly in new quarters, at the time of his death. He will be remembered best for his work on trichomoniasis in cattle, housing problems and poultry husbandry, being with the late Dr. Black, of Reading, the first to report on the successful applications of artificial insemination in fowls (*Gallus domesticus*).

NEWS and VIEWS

Plant Physiology at the Imperial College of Science and Technology : Prof. Helen K. Porter, F.R.S.

DR. HELEN K. PORTER, who has recently been appointed to the chair of plant physiology in the Imperial College of Science and Technology, London, is the first woman to hold a chair in the College. After graduating from Bedford College, London, in 1921, she spent a year in the Department of Organic Chemistry at the Imperial College, and was then appointed research assistant in the Department of Botany. Ten years later she joined the staff of the Research Institute of Plant Physiology attached to the Imperial College, and concentrated primarily on research in the field of carbohydrate metabolism. Shortly after the Second World War she spent a year in Washington University, St. Louis, studying enzymological methods. The subsequent development of her work, in collaboration with a group of colleagues and postgraduate research students with the support of the Nuffield Foundation, led to the opening in 1953 of an enzymology laboratory in the Institute of Plant Physiology, to accommodate a research group under Dr. Porter's direction. In 1956 she was elected to Fellowship of the Royal Society. In 1957 Dr. Porter was appointed to a new readership in enzymology at the Imperial College.

Burden Neurological Institute : Prof. F. L. Golla

PROF. F. L. GOLLA, director of the Burden Neurological Institute, Bristol, since 1939, is to retire. Prof. Golla, who followed Sir Frederick Mott as director of the Central Pathological Laboratory at the Maudsley Hospital, London, has for many years been a leading figure in neuropsychiatric research. Primarily a physiologist by training, his interests have extended into endocrinology, biochemistry, pharmacology and psychology, while his medicine has been constantly refreshed by gleanings in the German, French and Italian literature. His erudition is immense. In 1939 Prof. Golla moved to Bristol to start the Burden Neurological Institute, which, under his direction, has become widely known throughout the world.

Of Prof. Golla's research achievements, one of the most remarkable was his early application of the electroencephalograph to the study of neurological and psychiatric disorders, and, ably assisted by Dr. Grey Walter, he established the diagnostic value of the technique in cases of cerebral tumour and other lesions of the brain. He was also a pioneer in attempting the surgical treatment of epilepsy by the removal of epileptogenic foci, and played an important part in the development of electro-convulsive therapy. Many generations of students at the Maudsley Hospital remember with gratitude the inspiration of his lectures on the physiology of the nervous system. He has a style of his own and combines a keen critical capacity with a breadth of vision that is unique. In 1950 there appeared a volume entitled "Perspectives in Neuropsychiatry", which was published by old pupils and colleagues as a present for Prof. Golla's seventieth birthday. Always full of new ideas, he has found his pleasure and inspiration in his work and cares little for publicity or personal rewards.

Dr. W. Ross Ashby

DR. W. ROSS ASHBY, who now succeeds Prof. Golla, was previously director of the Research Laboratory at Barnwood House, Gloucester. He was educated at Cambridge and St. Bartholomew's Hospital and was at one time engaged as a pathologist at the Watford Peace Memorial Hospital and as a house physician at Bethlem. He is probably best known for his work on the 'homeostat', an electronic device designed to parallel the homeostatic mechanisms of the brain. His interest in the behaviour of neuronal nets led to the writing of the book, "Design for a Brain", which is very widely known.

Bell Telephone Laboratories Appointments : Dr. James B. Fisk

DR. JAMES B. FISK, executive vice-president of the Bell Telephone Laboratories, has been elected president as from January 1. Dr. Fisk succeeds Dr. Mervin J. Kelly, who has been elected chairman of the board of directors. Dr. Kelly has served as president of the Laboratories since 1951. Mr. Estill I. Green, vice-president in charge of systems engineering, is to be executive vice-president as from January 1.

Dr. Fisk, who has been associated with the Bell Laboratories for nearly twenty years, has combined a distinguished career in industrial research with outstanding service to the Government in the field of science. He was director of the Division of Research of the Atomic Energy Commission in

1947–48, and Gordon McKay professor of applied physics in Harvard University during 1948–49. He also served for six years on the General Advisory Committee of the Atomic Energy Commission. He is vice-chairman of President Eisenhower's Science Advisory Committee and has served on other government committees. He is a member of the U.S. National Academy of Sciences. He joined the technical staff of the Bell Laboratories in 1939, and during the Second World War he headed the Bell Laboratories group engaged in developing microwave magnetrons for high-frequency radar. After the War he was in charge of electronics and solid-state research.

Dr. M. J. Kelly

Dr. Kelly is one of America's leaders in the field of industrial research. He began his Bell System career in 1918 as a research physicist with the research division of the Western Electric Company's engineering department. This department was later incorporated as the Bell Telephone Laboratories. After serving as director of vacuum tube development and as development director of transmission instruments and electronics, he was elected director of research in 1936. He became executive vice-president in 1944 and president of the Laboratories in April 1951. He has had wide experience not only in research and development programmes relating to communications, but also in projects for the Armed Forces. In the course of the Second World War, the Bell Laboratories were devoted almost completely to military research and development programmes, all of which were under Dr. Kelly's guidance, and he was awarded the Presidential Certificate of Merit. Since the War he has held many public service appointments in Washington, particularly with the Atomic Energy Commission, the Department of Commerce and the Department of Defense. He is a member-at-large of the Defense Science Board. He has been awarded the James Forrestal Memorial Award of the National Security Industrial Association and will receive the 1959 John Fritz Medal for "his achievements in electronics, leadership of a great industrial research laboratory, and contributions to the defense of the country through science and technology". Dr. Kelly is also active in the field of education. He is a life member of the Massachusetts Institute of Technology Corporation and a member of its Executive Committee; a trustee of Stevens Institute of Technology; and serves on advisory committees at M.I.T., New York University, Case Institute of Technology, Columbia University, and the New York City Board of Education. He is a member of the New York City Health Research Council, a trustee and member of the corporation of Atoms for Peace Awards, a trustee of the Alfred P. Sloan Foundation and a member of the U.S. National Academy of Sciences.

Mr. E. I. Green

Mr. Green has a long record of distinguished engineering experience and achievement, including more than seventy patents granted for his inventions. He is also the author of many articles on scientific and personnel subjects. He began his career in 1921 with the American Telephone and Telegraph Company's development and research department, and with that department transferred to the Bell Laboratories in 1934. For many years he specialized in planning the development of new transmission systems, and services and facilities for special customers. During the Second World War he was engaged in development work on radar testing apparatus and other electronic equipment. He was appointed director of transmission apparatus development in 1948 and headed the development of systems components, including electronic components for transistorized systems. In 1953 he was elected director of military communications systems, in charge of planning and development in that area. He became vice-president of the Bell Laboratories in charge of systems engineering in June 1955. In that post he has been responsible for all Bell Laboratories work related to the systematic analysis and planning of future communications developments and systems.

The Royal Society: Tercentenary Celebrations

On November 28, 1660, a group of originally minded men meeting together in the City of London decided to form themselves into a scientific society. King Charles II, being informed of this, constituted himself the formal Founder, and the new society, now the premier scientific society in the world, came to be known as the Royal Society of London, or more generally, 'The Royal Society'. The Society, the apartments of which are now in Burlington House, Piccadilly, announces that it proposes to celebrate the tercentenary of its foundation during July 18–26, 1960, and a committee, with Sir Cyril Hinshelwood, president, as chairman, has begun to arrange appropriate celebrations to mark this event. Leading scientists from all nations are expected to attend the meetings, which are to include special visits to the City of London and the Universities of Oxford and Cambridge, both of which have important links with the Society's development over three centuries. The members of the Committee are: Sir Cyril Hinshelwood (*chairman*), Lord Adrian, Sir Gavin de Beer, Prof. P. M. S. Blackett, Sir Lawrence Bragg, Sir Lindor Brown, Sir Charles Dodds, Sir Alexander Fleck, Sir Howard Florey, Prof. W. V. D. Hodge, Sir Harry Melville, Sir William Penney and Dr. H. G. Thornton. The secretary to the Committee is Dr. D. C. Martin (assistant secretary of the Royal Society).

Nuffield Collection of Meteorites at the British Museum (Natural History)

A substantial part of Dr. H. H. Nininger's collection of meteorites, consisting very largely of falls hitherto unrepresented in British collections, has been purchased for the British Museum (Natural History) through a gift of £50,000 from the Trustees of the Nuffield Foundation, to celebrate the centenary of Prof. N. Story-Maskelyne's appointment as first keeper of minerals. To the 837 falls hitherto represented in the Museum, the Nuffield purchase adds a further 197, bringing the total to 1,034, or about 67 per cent of all known falls. Together with the 72 additional specimens of falls already represented, this greatly strengthens the reserves available for further exchanges. This large accession of meteorites is to be known as the Nuffield Collection. The British Museum's collection of meteorites is the largest and among the oldest in the world, dating back to 1776 when a specimen of the stony-iron found at Krasnojarsk, Siberia, was presented by the Russian Academy of Sciences. For many years the collection remained a relatively minor one, until Prof. N. Story-Maskelyne became the first keeper of minerals in 1859. A judicious series of exchanges and purchases soon improved the status of the collection, and when

G. T. Prior published his "Catalogue of Meteorites" in 1923 it held a clear lead over all others. In the past thirty-five years, the intensive search for meteorites sponsored by Dr. H. H. Nininger in the United States has resulted in a large number of new finds, but has also made the acquisition of new falls by purchase increasingly difficult for the Museum. Although a programme of exchanges with other museums has been vigorously pursued, the increase in falls represented in the British Museum has hitherto not kept pace with the increase in known falls. The scientific aspect of the Nuffield gift is of importance because meteorites constitute the only extra-terrestrial material available for detailed study, and an exact knowledge of their composition and structure is important for the cosmogony of the solar system.

Skomer Island as a Nature Reserve

WITH the co-operation of the West Wales Field Society, the Nature Conservancy is purchasing the island of Skomer as a National Nature Reserve. Skomer, 722 acres, is the largest of the islands off the Pembrokeshire coast. It is the landward edge of the ridge of varied igneous rocks of Ordovician age, jutting west from the mainland through Skomer to form Grassholm (famous for its colony of 10,000 pairs of gannets). Each year great numbers of sea-birds breed on Skomer, as well as a strong colony of the Atlantic grey seal. Probably the most notable breeding species is the Manx shearwater, a bird scarcely found on the mainland, but nesting in tens of thousands on Skomer and Skokholm. The puffin colony is, next to that of St. Kilda in the Hebrides, probably the largest in the British Isles. The island is also well known for the Skomer vole, which differs from the common bank vole in its larger size, extreme tameness and brighter colour. Skomer is being leased to the West Wales Field Society, which made an extensive field survey of the island in 1946, described in "The Island of Skomer" (West Wales Field Society, Orielton, Pembroke, 1950. 18*s*.). Persons requiring facilities on the island should communicate in advance with the Society, c/o The Hon. Warden, Orielton, Pembroke. Scientific investigations on the reserve may be arranged with the Regional Officer for South Wales of the Nature Conservancy, Department of Zoology, University of Swansea, Singleton Park, Swansea.

The British Steel Industry

POLITICAL and Economic Planning has rendered a real service by summarizing in Broadsheet No. 428 (November 28, 1958) "The Development of the Steel Industry", without entering into political controversy regarding ownership and control, the problems involved in planning the development of the industry whatever form of organization is finally adopted. The most important issue regarding the organization of the industry is simply whether one form of organization is better able than another to help the industry to provide the steel that is needed for the growth of the rest of the economy. Decisions will be required from time to time as to the total capacity of the industry and also detailed decisions on the building of individual plants. The former will have to be based on estimates of the growth of industrial production, which in post-war conditions are exceedingly difficult to make. The latter will continue to be influenced by assessments of future prospects for supply and demand, whether the industry is privately owned and controlled, or privately owned but supervised by an official board as at present, or both publicly controlled and publicly owned. Pricing policies will affect both the total demand for all kinds of steel and the demand for particular products. Location will be a matter of controversy because argument will continue that one location is better or worse than another not only on the grounds of productive efficiency, but also on account of the social issues involved in siting such large and vital industrial units. The development of the European Economic Community and the possible association of Britain with it will affect decisions about the capacity and location of the British industry, and particularly the question of the acceptance of some imports as against the objective of self-sufficiency in steel. These are the real economic issues, and questions of ownership and control are significant economically only in so far as they contribute to their solution.

Future of Television in Britain

SOME of the factors which should be taken into account when considering the future development of television are set out in a broadsheet, "Prospects for Television" (No. 427, October 31, 1958), issued by Political and Economic Planning. Without seeking to argue that a certain type of development should occur or to suggest who would be best able to undertake it, the broadsheet shows that there are many possibilities and that television in Britain need not be as limited as is sometimes imagined. The four remaining channels in Band 3 could be used to provide another television service for most of the country as soon as the Government decided to make them available (subject to available finance), but this would utilize all available very high-frequency channels and would reinforce the strength of present standards while leaving untackled the problems of higher definition and colour and of ultra high-frequency. It might also prevent the development of colour or higher definition on very high frequency, and would leave no room for parallel transmissions if further services were required. Two programmes could be provided on the remaining very high-frequency channels, each serving nearly two-thirds of the population, while allowing some local low-powered stations of Britain, but national coverage would not be achieved and there could be no further programmes or room for manœuvre. It is unlikely that the present very high-frequency channels or their limited extension will prove adequate for the future, and the main hope seems to lie in the development of the ultra high-frequency bands, which will leave room for a wider entry and allow a higher definition system and colour to be introduced when wanted. It should be possible to have quite a number of national and local television stations if they are wanted, and the proposed extension of the hours of television would permit the provision of a wider range of programmes for differing tastes but would add considerably to costs.

Nuclear Power Station on the Lleyn Peninsula

INTENSE opposition to the building of the nuclear power station at Edern in the Lleyn Peninsula is strongly brought out in the annual report of the Caernarvonshire Branch of the Society for the Preservation of Rural Wales. To protect the beauty and tranquillity of this rare and unspoilt coast, the National Parks Commission declared it an "area of outstanding natural beauty" on September 13, 1956; this was confirmed by the Minister of Fuel and

Power on May 27, 1957. Opposition to the new station is based not only on the despoliation of natural beauty but also because "the influx of workmen from outside, the rapidly changing levels of employment and its insecure basis, will upset agriculture and other stable industries by the uneven pattern of employment and create great disturbance". The Society's arguments have been set out in a specially prepared booklet, which can be obtained from W. Twiston Davies, Plas Hebog, Beddgelert, North Wales.

Curator

ALTHOUGH the museum profession is now attracting to its ranks more people than ever before, there are very few publications devoted to museology. For this reason alone the appearance of the quarterly periodical, *Curator* (1, No. 1, January 1958. Pp. 96. Annual subscription: 5 dollars), issued by the American Museum of Natural History, New York, is a welcome addition to the scanty literature. The days when a museum curator was a recluse, generally non-academic, are past, and the present-day official is relatively young, a specialist in a cognate subject and fully alive to the new demands of the public. There is thus no need for the editors to apologize for this new journal, and indeed the profession should be grateful to them for the initiative shown. A high standard of production was insisted upon for the first issue and this has been fully maintained throughout the year in the course of which ninety-four articles have been published, all of them of use to the curator who, unlike many of his academic colleagues, has to be proficient in a great variety of directions. *Curator* gives a general account of his activities, summarizes and reduces to print many of the thoughts in the mind of curators to-day and offers much information regarding new materials and techniques.

Maser Observations in Radio Astronomy

IN a paper presented at the one-hundredth meeting of the American Astronomical Society (and reported briefly in *Astron. J.*, **63**, 301; 1958), L. E. Alsop, J. A. Giordmaine, C. H. Mayer and C. H. Townes report what is possibly the first attempt to use maser techniques in radio astronomy. The maser amplifier is a three-level Bloembergen type, with a 0·1 per cent concentration of Cr^{3+} in ruby serving as the paramagnetic medium. The ruby crystal is mounted in a double resonant microwave cavity in liquid helium at 1·4° K. and in a magnetic field of 3,500 oersteds. The optimum signal-to-noise ratio for the system is obtained with a gain of about 20 decibels. The maser is used as a pre-amplifier and is mounted near the focal point of the 50-ft. reflector of the U.S. Naval Research Laboratory. The results obtained show an improvement factor of about ten in signal-to-noise ratio over the same installation without the maser pre-amplifier, in accordance with the expected low noise characteristics of maser amplifiers. Observations were made of Venus, Jupiter and the nebula NGC 4486, and they demonstrate the feasibility of applying maser techniques to radio-astronomical observations.

Permanent Graticules

WORK at the Reference Standards Laboratories of the Australian Commonwealth Department of Supply has culminated in the introduction of a new method for the production of graticules, known as the 'interstitial graticule' process. The method employed is of considerable interest, and the product will undoubtedly find a number of applications, particularly in cases where permanence is the prime requisite (*Aust. J. App. Sci.*, **9**, 207; 1958). The desired pattern is first produced on the surface of the glass. By a process of electrolysis at an elevated temperature the pattern is transferred in ionic form below the glass surface. Subsequent treatment involving chemical reduction converts the 'ionic' image to metal and the graticule pattern then becomes readily visible and is as stable as the glass itself. By suitable choice of metal and conditions of processing the final pattern may be black or coloured, transparent or opaque. The inventors of the process, A. J. C. Hall and J. C. Hayes, have recently been awarded the Waverley Gold Medal and Prize by the journal *Research* for an essay on their work.

Records of Nodulation in *Coriaria*

IN referring to the root nodules borne by *Coriaria* spp. (*Nature*, **182**, 474; 1958), Dr. Bond commented that although their occurrence in New Zealand is known, there seem to be no records in the literature. Mr. R. E. R. Grimmett (formerly superintendent of the Rukuhia Soil Research Station, Hamilton, N.Z.) has directed attention to an article, by him, using the pseudonym "Cryptos" and published in the August 1944 issue of *Forest and Bird*, the journal of the New Zealand Forest and Bird Protection Society. Under the title of "The Much-maligned Tutu"—the latter being the Maori name for *Coriaria* spp.—Mr. Grimmett recorded the regular occurrence of nodules on a species of *Coriaria* (now identified as *C. arborea*) in the Wairarapa district, and testified to the faculty of this and other species of the genus for colonizing raw mineral soils and improving fertility, facilitating the eventual establishment of forest. Like Dr. Bond, Mr. Grimmett referred to the paucity of native legumes in New Zealand and envisaged the possibility that *Coriaria* has been a main native source of biologically fixed nitrogen in that country. The field observations which he cited are in excellent accord with such results of laboratory experiments as are available.

International Grassland Congress

THE eighth International Grassland Congress will be held in Reading during July 11–21, 1960. Reading will prove to be a very appropriate town, since it is within easy reach of several important centres of agricultural research. Pre-Congress tours of grassland areas and research institutes are being planned. The main problems to be discussed are: pasture management and fertilizing; plant breeding and genetics; conservation—recent developments; problems of tropical grassland; estimation of grazing intake; biochemistry of pasture plants; hormone stimulation of grazing animals; special statistical techniques. The organizing committee is commissioning the majority of papers to be presented to the Congress, but it will also consider requests from research workers who wish to present papers of particular interest. Further information can be obtained from the Secretary, Eighth International Grassland Congress, Reading, Berks.

Symposium on Interferometry

AN international symposium on interferometry is to be held at the National Physical Laboratory, Teddington, Middlesex, during June 9–11. The symposium is intended for specialists and will not deal primarily with technical applications. There will be four half-day sessions devoted to the presentation of papers and to discussion, and a fifth session for demonstrations. About twenty main papers have been invited and will be printed and circulated in advance. Additional short contributions will be welcomed in the form of contributions to the discussion on the main papers, or in the form of demonstrations. The main papers, the discussions, and notes on the demonstrations will be collected and published after the symposium in one volume. Attendance is by invitation; applications should be made to Mr. L. H. McDermott at the National Physical Laboratory.

University News: California Institute of Technology

A GRANT of 73,594 dollars from the U.S. National Foundation (formerly the National Foundation for Infantile Paralysis) has been made to Dr. Renato Dulbecco who, with Dr. Marguerite Vogt, is investigating virus inheritance in experiments involving polio virus mutations. Another grant, of 33,943 dollars, has been made by the National Foundation to Prof. Linus Pauling, for investigations on the structure of nucleic acids.

Nottingham

THE University of Nottingham has received an offer of £100,000 from Rolls-Royce, Ltd., to endow a chair of thermodynamics in the Faculty of Applied Science. This chair is to be established by the Company in recognition of Lord Hives's contribution to engineering science, and will be known as the Hives chair of thermodynamics. It is hoped to encourage the training of an increased number of technologists and the development of a strong research school in thermodynamics. The University plans to increase its output of mechanical engineers by 250 per cent in 1965, and new laboratories to make this possible are under construction. One of these new laboratories will accommodate thermodynamics, fluid mechanics and heat transfer and occupies some 30,000 sq. ft. The new professor will be responsible for these laboratories and the development of researches in these fields.

Announcements

THE Council of the Institution of Mechanical Engineers has awarded the 1959 James Watt International Medal to (the late) Sir Claude Gibb as an engineer who achieved international recognition both by his work as a mechanical engineer and by the ability with which he applied science to the progress of mechanical engineering.

DR. MAX A. LAUFFER, professor of biophysics and dean of the Division of Natural Sciences in the University of Pittsburgh, has been awarded the 1958 Pittsburgh Award of the Pittsburgh Section of the American Chemical Society. Recently his main researches have been on the hydration of viruses and proteins, and the relationship between their physical, chemical and biological properties.

MR. A. BARCLAY, keeper of the Department of Chemistry, and Mr. E. W. White, deputy keeper in the Department of Aeronautics in the Science Museum, South Kensington, are to retire on March 31. Dr. S. E. Janson, deputy keeper in the Department of Chemistry, has been appointed keeper, in succession to Mr. Barclay and Mr. F. Greenaway and Mr. W. Winton have been appointed deputy keepers from April 1.

A TRANSLATION Service has recently been set up by the Iron and Steel Institute with the collaboration of several large companies and of the British Iron and Steel Research Association. The Service is open to both members and non-members in Great Britain and abroad. Some 530 translations are already available, a large proportion of them from German or Russian, and a classified list of the translations made in the first year is now available; it is kept up-to-date by fortnightly lists (with classified cumulations every six weeks). Inquiries should be addressed to the British Iron and Steel Industry Translation Service, Iron and Steel Institute, 4 Grosvenor Gardens, London, S.W.1.

A course for senior technical executives in industry is being held at the Harwell Reactor School during June 15–25, the fee being 50 guineas. Forms of application and further details can be obtained from the Reactor School, Atomic Energy Research Establishment, Harwell, near Didcot.

A SYMPOSIUM on Boundary Problems in Differential Equations, with especial reference to recent developments in this field, will be held by the Mathematics Research Center, United States Army, at the University of Wisconsin during April 20–22. Further information can be obtained from R. E. Langer, Director, Mathematics Research Center, U.S. Army, 1118 West Johnson Street, Madison 6, Wisconsin.

A CONFERENCE on Electrically Exploded Wires, sponsored by the Thermal Radiation Laboratory of the Geophysics Research Directorate of the U.S. Air Force Cambridge Research Center, will be held at the Somerset Hotel, Boston, Massachusetts, during April 2–3. Invited and contributed papers on both theory and uses of exploding wires will be presented. Further information can be obtained from W. C. Chace, Thermal Radiation Laboratory, CRZCM, Geophysics Research Directorate, Air Force Cambridge Research Center, Bedford, Massachusetts.

THE English Electric Valve Co., Ltd., is holding an exhibition at the Kensington Palace Hotel, London, during March 17–21. The display will be devoted to modern valve design technique in the fields of radar, communication, transmitting, broadcasting—both sound and vision—and instrumentation, together with new types of storage tubes. Further information can be obtained from A. J. Thoroughgood, English Electric Valve Co., Ltd., Waterhouse Lane, Chelmsford, Essex.

A SPECIAL short course in Stereospecific Polymers and Block and Graft Co-polymers is being held in the Department of Chemical Technology of the Bradford Institute of Technology on February 27 and 28. Prof. C. E. H. Bawn will lecture on the preparation of stereospecific polymers; Dr. I. Goodman on stereochemical structure and polymer properties; Dr. C. H. Bamford on the preparation of block and graft co-polymers; and Dr. W. Cooper on the properties and uses of block and graft co-polymers. The fee for the course is 45*s*. Application forms can be obtained from the Registrar, Institute of Technology, Bradford.

ERRATUM. In the communication entitled "Penicillin Derivatives of *p*-Aminobenzyl Penicillin" in *Nature* of January 17, p. 180, the units throughout should be "u./ml.", not "μ/ml." as printed.

MECHANIZATION OF THOUGHT PROCESSES

A SYMPOSIUM entitled "The Mechanization of Thought Processes" was held at the National Physical Laboratory during November 24–27. About two hundred invited delegates came from thirteen different countries to listen to, and discuss, papers on a wide range of topics related to 'artificial intelligence'. Associated with the symposium was an exhibition of devices and machines related to the general theme.

Dr. M. L. Minsky, of the Massachusetts Institute of Technology, gave the opening paper, which was concerned with "Heuristic Programming". Heuristic methods can be distinguished from the straightforward methods of solving a problem by the fact that they cannot be guaranteed to work. They are not 'algorithms'. The paper dealt with programmes for computers rather than with special machines, because any machine that can be fully specified can certainly be simulated on a digital computer, and trials by computer are less expensive.

The special features of heuristic methods discussed were 'pattern recognition', 'learning', 'planning ahead' and the use of analogies or models. These features were illustrated by a proposed programme for proving theorems in Euclidean geometry, where the model consists of actual constructions of points and lines. When tried out on the theorem that 'the base angles of an isosceles triangle are equal', it provided an unusual proof, using the congruence of the triangle to its mirror image.

There were two other papers on the general principles of intelligent machines, by Dr. D. M. MacKay, of King's College, London, and Dr. J. McCarthy, of the Massachusetts Institute of Technology. Dr. MacKay's paper examined the problems of obtaining intelligence in machines, and of evaluating it and distinguishing it from mere ability to calculate. He was led to the conclusion that one needed a hybrid system consisting of a digital decision process with an analogue process for evaluating 'weight' of information and proximity of a solution, etc. Several of the later papers concerned such devices.

Dr. McCarthy described a computer programme which he is developing, called the 'advice taker'. This programme, when given a set of statements about the world, is intended to deduce conclusions about action to be taken. In the discussion, some speakers felt that the proposed 'machine' would be too logical, and that practical decisions are not made in this way. It was agreed that the final answer would be given when the programme could be shown to work, or not, as the case may be.

It is not possible to describe here all the papers that were read and discussed. They can perhaps be divided into four groups, and some from each group will be mentioned. The groups are: (1) proposed mechanisms for intelligent machines, not necessarily related to neural mechanisms; (2) proposed mechanisms for intelligent machines which bear some relation to what is known of neural mechanisms; (3) the lessons to be learnt from the study of perception; (4) a number of related topics and applications.

Perhaps the most interesting mechanisms discussed at the symposium were those that attempted to reproduce some of the known constructional features of the brain. They were contained in papers by Dr. A. M. Uttley, of the National Physical Laboratory, Dr. F. Rosenblatt, of Cornell Aeronautical Laboratories, and Dr. W. S. McCulloch, of the Massachusetts Institute of Technology.

Dr. A. M. Uttley's 'conditional probability computer' embodies a classifying network, or 'tree', and a set of counters to record the number of instances of each possible state of the input channels. These counts are recorded in a logarithmic scale, so that their differences represent the logarithms of estimated conditional probabilities. The conditional probabilities are used to infer patterns at the input when only part of the pattern has actually been presented to the machine. In the paper presented to the symposium, this work was developed by considering how neural networks, with their connexions in some respects random, could perform in a way similar to the highly organized electronic model.

Dr. F. Rosenblatt described recent theoretical work on the behaviour of the 'perceptron'. This is a 'neural' network in which a large population of 'neurons' have random connexions to the inputs, and their connexions to the outputs are paralleled by feed-back connexions which modify the parameters of the 'neuron' so that frequent stimulation of an output will reinforce the neurons which feed this output. The hypothetical neurons assumed by Rosenblatt obey linear equations, for convenience; but computer simulation has shown that they would work with a wide range of characteristics.

Dr. W. S. McCulloch's paper was concerned with hypothetical neurons working with binary signals, and with a threshold—the well-known 'Pitts and McCulloch' neurons. It did not attempt to describe what happens in the brain, but explored switching circuit design using these particular switching elements. The problem considered was how to make switching circuits which are insensitive to variations of threshold.

Dr. O. G. Selfridge, of the Massachusetts Institute of Technology, described a process which was not related to neural mechanisms, but which would adapt and improve itself to handle recognition problems. The process, called a 'pandemonium', was described in rather anthropomorphic terms, but this was perhaps less obscure than an abstract description would have been. The pandemonium contains an assortment of 'demons' each responsible for looking out for a particular feature in the input. Some demons may look for features in the output of lower demons. At the highest level in the system, the strongest output of any demon is detected by a decision demon. Processes were described for inventing demons, making them more or less powerful according to experience, and so forth. A practical example is under development; this is a pandemonium for the translation of manually keyed morse.

A very interesting paper by Dr. Ross Ashby, of Barnwood House Hospital, Gloucester, showed that habituation can be demonstrated in a mechanism without any detailed assumptions about its construction. The only assumptions made were of a behavioural kind. By habituation is meant the decrease of response to a stimulus when it is regularly repeated. An indication was given of the circumstances in which extraneous disturbances could cause de-habituation.

Among the several papers giving the point of view of biologists was one by Dr. H. B. Barlow, of the

University of Cambridge, which treated the coding of signals in sensory mechanisms. There is evidence of mechanisms operating at low levels in sensory pathways to reduce the amount of redundancy in the vast number of parallel information channels. Unlike the recoding proposed by Shannon for communication channels, the aim is not to remove all redundancy, but to reduce the number of pulses on any given channel, and to reduce correlation between channels. For two binary channels, the specification of such a coding device is very simple, and a model of this device was shown in the exhibition.

Among the specialized topics discussed was automatic programming, to which a morning's session was devoted. Dr. Grace Hopper, of Remington Rand, Ltd., gave the opening paper, and the session was rounded off by a paper from Dr. A. P. Ershov, of the Academy of Sciences of the U.S.S.R.

An afternoon's session was devoted to mechanical language translation, and Dr. Ershov, at short notice, said something about the groups working on this subject in the U.S.S.R.

Unusual fields for mechanization formed the subject of several papers. Dr. L. Mehl, of the École Nationale d'Administration, Paris, spoke on automation in the legal world. He described a machine for retrieving legal information and a machine for legal argument. The limitations of such machines are that they are incapable of evaluating data, or of developing the principle of law, so they cannot be a substitute for the jurist.

Dr. F. Paycha, of Paris, spoke about the logical structure of medical diagnosis, emphasizing the vast volume of facts on which it is based, and the need for mechanization to reduce the chance of an error. In the discussion which followed, the question was raised of how far probability considerations should be allowed to influence diagnosis.

Speech recognition was the subject of two papers. Prof. D. B. Fry and Mr. P. Denes, both of University College, London, described how linguistic information has been brought into the problem of speech recognition. A machine capable of handling 13 English phonemes and using digram frequencies to make a decision was shown in the exhibition. A paper by Mr. P. Ladefoged, of the University of Edinburgh, reviewed the whole field of speech perception, making the particular point that speech is not, in any sense, a sequence of small discrete elements.

In the analogous field of visual pattern recognition, a paper was read by Dr. W. K. Taylor, of University College, London.

Other papers dealt with literature searching, the mechanization of administration, and learning in animals, in addition to the subjects mentioned above.

The general impression given by the symposium was that in none of the fields of study is there any finality as to the basic approach to the problem. In the field of intelligent machines, there was a wealth of suggestions, but none of these has yet reached the stage of a successful test. It was also evident that many suggestions that can be made for machines to solve problems or perceive patterns may fail because the number of individual units in the machine is too large and that any practical machine must include some trick to achieve economy of equipment.

The modern theory of automata began with A. M. Turing's proof that universal computing machines were possible. Dr. Turing's ideas, and those of J. von Neumann, led to the construction of electronic computers, which are the working tools of the experimental approach to artificial intelligence. It seems possible that a further great advance in the development of intelligent machines will soon be made.

The *Proceedings* of the symposium, including the papers read, together with the discussion, will be published by H.M. Stationery Office in due course.

D. W. DAVIES

DEVELOPMENT OF ELECTRIC CABLES

MR. S. E. GOODALL delivered his presidential address before the Institution of Electrical Engineers on October 9. His subject was electric cables, and a substantial part of his address was devoted to reviewing the history of their development.

It was in the year 1812 that the first experiments were made in applying a soluble material, said to be india rubber, to the insulation of copper wires. The great initial development of the electric telegraph took place as a means of inland communication and the circuits employed were almost wholly composed of overhead, open-wire, lines. It was the timely discovery of the excellent properties of gutta percha as an insulant and its practical application to electric cables by Werner Siemens that initiated the development of submarine telegraph cables and indeed of cables generally. The year 1851 saw the first cross-Channel cable in operation, and fifteen years later the first successful telegraph cable spanned the Atlantic Ocean. The pioneer of the electric power cable was Sebastian de Ferranti. The transmission of power by alternating current at 10,000 volts from the Central Station at Deptford to the West End of London was effected by concentric cables of entirely novel design. Oil-impregnated paper was the dielectric, and the type of construction devised by Ferranti remained the basis of high-voltage power cable design for half a century. By 1900 single-core and three-core impregnated paper lead-sheathed cables were in regular manufacture in Britain.

The manufacture of telephone cables developed rapidly from about 1890. Multi-circuit lead-covered cables when first introduced were filled with insulating material such as paraffin wax, but their electrical characteristics were soon greatly improved by the adoption of the dry-core technique, in which advantage is taken of the air interstices to obtain lower electrostatic capacitance. The first cables used for long-distance telephony were simply adaptations of telegraph cables and used gutta percha as a dielectric. For gutta percha, balata was later substituted and this held the field for submarine purposes until comparatively recently.

Two very important developments in high-voltage power cables occurred during the 1920's. The major factor tending to initiate breakdown in high-voltage cables had been traced to ionization in voids in the dielectric, and the formation of voids had been demonstrated to be associated with the thermal expansion and contraction of cables under varying conditions of load. Improved design and better techniques of impregnation proved to be insufficient to remove the inherent electrical weakness resulting from heating cycles. The first effective remedy was devised by Emanueli, who, in 1920, employed a thin mineral oil as a liquid impregnant applied under pressure from reservoirs at predetermined points in the cable system. An alternative method of suppressing ionization in voids, invented at about the same time, was the use of an inert gas at high pressure. This development did not proceed very rapidly and was seriously interrupted by the Second World War. There are, however, now many important installations of super-tension gas pressure cables.

The distribution of electricity in buildings was first effected by wires insulated with paraffined cotton, but it was not long before rubber was adopted as the insulant. Some indication of the early rate of development of the distribution of electricity to domestic and industrial premises is given by the fact that in 1882 the Society of Telegraph Engineers and Electricians issued their first "Rules and Regulations for the Prevention of Fire Risks from Electric Lighting".

Although the techniques of cable manufacture were being steadily developed and improved, there had been, up to the outbreak of the Second World War, little change in the basic materials and processes. During the Second World War and since, very far-reaching changes have taken place. Plastics and synthetic rubbers have been introduced, some of these materials having excellent electrical characteristics together with satisfactory mechanical properties, and a substantial proportion of the electric cables now manufactured employ these new insulants. It was the development of radar during the Second World War that evoked the urgent demand for cables which would transmit satisfactorily very high-frequency currents, and polythene was the material which enabled this demand to be met. The drastic reduction in the available supplies of natural rubber which developed as the War progressed was the incentive in the search for synthetic substitutes. Polyvinyl chloride, commonly known as P.V.C., is a war-time product which is now firmly established in cable-making practice.

In addition to the introduction of new insulating materials there have been, since the end of the War, important developments in manufacturing methods. As an example of this may be cited the new method of coating wires known as continuous vulcanization. A well-established method of applying the rubber covering to wires involves the continuous interleaving of a group of wires moving longitudinally in parallel between two thin ribbons of rubber. The passage of this layered ribbon between suitably grooved rollers produces individual insulated wires with, of course, seamed coverings. The modern alternative to this is known as continuous vulcanization.

In this process rubber compound is forced on to the wire as a seamless cylindrical coating in the extruding 'head' of a rotary-screw extrusion machine through which the wire is passing at fairly high speed. Immediately on leaving the head the covered wire is passed into a long well-lagged steel tube which contains high-pressure steam, and in this vulcanization takes place. In this process the finished core is produced to very close tolerances by the extensive utilization of electronic methods of automatic control.

Direct extrusion methods are employed for the covering of cables insulated with polyvinyl chloride and polythene. It is not practicable to use, for these synthetic materials, the same machines as are used for natural rubber coatings, but plants designed for polyvinyl chloride can with relatively slight modification be utilized for polythene.

Some important advantages, other than those of improved electrical characteristics, are associated with the use of the new plastics, but there are also limitations.

Polyvinyl chloride has good mechanical properties and, in addition, is strongly resistant to corrosion. For this reason it is used as an external, serving to protect from the corrosive effects of soil waters or of acids such as those produced when textile servings rot through bacterial attack. Wire insulated with polyvinyl chloride or polythene, however, is not capable of withstanding as great an electrical overload as can be tolerated by conductors insulated with vulcanized indiarubber. Ordinary grades of polythene melt at a temperature slightly above 105° C. Polyvinyl chloride, while it has no sharp melting point, becomes softer as the temperature increases and may suffer severe deformation under mechanical stress. The thermal characteristics of polythene can be considerably improved by exposing the material to neutron or electron bombardment. Such treatment effects cross-linkage between the molecular chains in its structure. This eliminates the sharp melting-point and the material becomes rubber-like at about 150° C. Irradiation is, however, expensive, and it appears unlikely that irradiated polythene will be available except for special applications.

Another important synthetic material is silicone-rubber. This material will operate indefinitely at 150° C. and flexibility is retained down to − 70° C. Its electrical properties are similar to those of natural rubber. Cables insulated with silicone-rubber have the unique property that, if exposed to fire, the residue of the insulation is largely pure silica, and after a fire such cables can be operated temporarily provided they are not disturbed.

Mr. Goodall's address ended with a brief review of the technical possibilities and objectives of cable making in Great Britain. The trend towards greater use of plastic materials would, he thought, undoubtedly continue, and there would probably be continued effort towards such reductions of dimensions as might be rendered possible by improved process control methods.

To be able to face intensifying competition from abroad both in the home and export markets, the industry must be prepared to face the consequences of rationalization of production, with consequent regrouping of manufacture and co-operation in one form or another among the different companies concerned. Cable users, on the other hand, must be prepared, in their own and in the national interest, to accept some measure of restriction of choice. The two bugbears of cable making are alternatives and variety, and the industry as a whole possesses surplus plant for many operations, although few if any of these operations are wholly obsolete. In effect, standardization must be directed towards the elimination of unnecessary complication rather than the inclusion of all the variants for which there might be a demand.

James Greig

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION, AUSTRALIA

CHEMICAL RESEARCH LABORATORIES

THE Commonwealth Scientific and Industrial Research Organization (Australia) has changed the status of one of its largest research groups, the Division of Industrial Chemistry, which has its headquarters at Fishermen's Bend, Melbourne. The Division will in future be known as the C.S.I.R.O. Chemical Research Laboratories, and its chief, Dr. I. W. Wark, becomes the first director of the Laboratories. Two of the largest Sections of the Laboratories will become Divisions (the name used for the major units of C.S.I.R.O.'s activities). Dr. A. L. G. Rees will become chief of the new Division of Chemical Physics and Dr. K. L. Sutherland will become chief of the new Division of Physical Chemistry.

These two new Divisions together with the remaining four major Sections will comprise the Chemical Research Laboratories. These sections and their officers-in-charge are as follows: Minerals Utilization (Mr. R. G. Thomas); Organic Chemistry (Dr. H. H. Hatt); Cement and Ceramics (Mr. A. J. Gaskin); Chemical Engineering (Dr. H. R. C. Pratt). The Foundry Sands Section will continue to be affiliated with the group.

Dr. Wark has been chief of the C.S.I.R.O. Division of Industrial Chemistry since its formation in 1940. Under his guidance this group has grown until it now has a research staff of one hundred and a total staff of three hundred.

More than a third of the research staff has been recruited from overseas, and about half of the Australians have studied abroad for higher degrees.

An adventurous outlook on research within the Chemical Research Laboratories has produced outstanding contributions in many phases of chemical discovery, both in basic science and in the solution of practical problems.

Some of C.S.I.R.O.'s more spectacular applications of science have come from the Chemical Research Laboratories. These include the process using cetyl alcohol for controlling evaporation from dams and reservoirs; the process for separating hafnium from zirconium which is of significance for atomic-powered submarines; and a process for recovering uranium from its ores.

Dr. Wark's own personal research was concerned with the theory of the flotation process for separating minerals from ores, which is of major importance to the mining industry. His pioneering work as a physical chemist in this field gained for him a worldwide reputation, and his book, "Principles of Flotation", first published in 1938, became recognized as a classic on the subject. He is a Fellow of the Australian Academy of Science. For many years he has taken a prominent part in the affairs of the Royal Australian Chemical Institute and has done much to gain a wider appreciation of the importance of chemistry and of science generally. He served as president of the Institute during the year 1957–58.

Dr. A. L. G. Rees, chief of the new Division of Chemical Physics, began his scientific career with a brief temporary lectureship in the University of Western Australia; then he became Beit Fellow at the Imperial College of Science and Technology, London. In 1941 he was awarded the Ph.D. of the University of London and joined the Philips organization in England as head of the Fundamental Research Group. He held this post until 1944, when he was appointed to C.S.I.R.O. to form the Chemical Physics Section. He has undertaken research into the structure and properties of materials. He is the author of many scientific papers on spectroscopy, electron diffraction, electron microscopy, luminescence and allied subjects. He is the author of a book—"Chemistry of the Defect Solid State" (Methuen, London, 1954). He is a Fellow of the Australian Academy of Science and of the Royal Australian Chemical Institute. He received the Institute's Rennie Memorial Medal in 1945 and its H. G. Smith Memorial Medal in 1951.

Dr. K. L. Sutherland, chief of the new Division of Physical Chemistry, began his research career on the froth flotation of minerals, which was supported by a group of mining companies, in the University of Melbourne. He joined C.S.I.R.O. in 1940 and continued his work on flotation, concentrating particularly on the kinetics of the process. He has gained world-wide recognition for his work in this field. In 1947 he was awarded the Davy Faraday Fellowship of the Royal Institution and worked in London for a period. Later, he was awarded the degrees of D.Sc. of the University of Melbourne and Ph.D. of the University of London. He returned to the Division of Industrial Chemistry in 1950. He recently collaborated with Dr. I. W. Wark in the revision of the second edition of Dr. Wark's book, "Principles of Flotation". He is a Fellow of the Royal Australian Chemical Institute. He received the Institute's Rennie Memorial Medal in 1943 and its H. G. Smith Memorial Medal in 1957. The University of Melbourne awarded him the Grimwade Prize in 1943 and the Syme Prize in 1948.

RURAL RESEARCH

THE lack of agricultural development in the comparatively well-watered section of tropical Australia has long presented an enigma. The region has been either hailed as a land of unlimited potentialities or written off as virtually worthless.

It is only in the post-war period that a systematic effort has been made to define the agricultural and pastoral potentialities of the land and solve the problems limiting its exploitation. Officers of the Division of Land Research and Regional Survey of the Commonwealth Scientific and Industrial Research Organization have been in the forefront of this effort and have shown already that large areas of Northern Australia are capable of agricultural development. By a series of broad-scale land-use potentiality surveys they classified and defined the land. Then Research Stations were established at two type locations to study crop and pasture production. The first of these was for dryland agriculture at Katherine, about two hundred miles south of Darwin, and the second was a joint irrigation venture with the Western Australian Department of Agriculture on the Ord River in the East Kimberleys.

Accounts are given in "Rural Research in C.S.I.R.O." of the successful outcome of research at these stations over the past decade (25, September 1958). Reasons for past failures have been explained, and with the new knowledge, crops such as sugar, rice, cotton and peanuts have been cultivated successfully under experimental conditions. Returns from peanuts as a major cash crop at Katherine and successes with subsidiary crops offer promise for the establishment of profitable mixed farming with associated livestock industries over large areas. At the Kimberley Research Station, sugar has done extremely well under irrigation, while rice, cotton and safflower are very promising. These experimental results must be supplemented by further economic data from farm-scale trials before settlement can be planned.

This information is now being sought as part of a joint venture with the Western Australian Department of Agriculture.

PARAPSYCHOLOGY

THE Institute for the Study of Mental Images was started informally in May 1956 as a private venture "in order to evaluate the status and behaviour of mental images not immediately related to sensory stimuli, and to pursue theoretical investigations in general psychophysical theory". An investigation of hypnagogic images is claimed to be in progress, assisted by a grant from the Parapsychology Foundation, New York. Three communications have now been published*.

In fairness to the authors, it must be made clear at once that their tripartite paper is a serious and learned essay in the philosophy of science—or in scientific philosophy, as it might better be termed in this case. Of its type, it is good. The technicalities are mainly in the language of physics, which most scientific readers will find more to their taste than symbolic logic; the text, though it could be clearer, compares well with that of the majority of disquisitions of this type; and the authors have avoided the more obvious traps. On the other hand, they have had to pay the price of extreme generality, abstraction and impartiality by seeming a little inconclusive.

But let them speak for themselves. The paper attempts "to bridge the considerable gap between psychiatry and advanced physics as the first step towards a psycho-physical theory of the world. A beginning is made by following Sir Arthur Eddington in questioning the usual *separability assumptions* which underlie all scientific investigations". (By "psychiatry" they clearly mean a class of psychological theory, not the day-to-day practice of the art.) Their purpose is "to outline a psycho-physical world theory which is both self-consistent and of sufficient generality to provide a framework for the discussion of all widely held opinions. . . . If this ideal could be realized, men might indeed become as little children, and continue throughout their lives to learn by experience, and to realize their mistakes, without becoming involved in paranoid ideological systems—whether religious, scientific, political or psychoanalytic".

They add, modestly enough, that their theory "has two of the chief characteristics of all paranoid phantasy, i.e., that it is self-consistent and incomplete".

The particular "widely-held opinions" exemplified are, of course, those related to the credibility (in the ordinary sense) of parapsychological phenomena and 'miracles' in general. The central point appears to be that it is illogical to claim that an alleged paranormal phenomenon is impossible by appealing to a scientific argument which rests on an assumption that absolutely precludes the phenomenon; one might as well say simply: "I do not believe it because it contradicts what I *do* believe". The psychiatrist, Dr. Michael Balint, is taken to task for falling into this elementary trap in connexion with the Lourdes 'miracles'. He is quoted as saying, in effect, that the criteria of cure (for example, that it must be instantaneous) are so unrealistic as to force the doctors concerned to distort the facts. It is true that Dr. Balint is out of his depth in these logical waters, or he would have realized that all arbitrary criteria (including that graven image, 'statistical significance') distort facts; but he is a practising clinician, and was clearly, though perhaps unwittingly, giving a clinical opinion rather than a sample of pure reason.

The authors of this paper, on the other hand, instead of taking sides, have attempted to found a system of thought in which it will not be necessary to take sides; in which what we now have to call either supernatural or bogus will be seen as natural. This ambitious project may be attempted in innumerable ways, varying from the easy to the impossible. The easiest way is simply to assert that all things are possible. The respectable empiricist who insists that no duly authenticated observation should be rejected on theoretical grounds evades being charged with this unlimited credulity at the risk of being challenged on his standard of due authentication. It is a weakness of this paper that it does not adequately meet the challenge.

So far as the authors' discursive style reveals, their basic strategy is to invoke the well-known common cause type of theory. Thus, if the universe is a gigantic statistical family tree, significant correlations of some kind should crop up occasionally in card-guessing experiments and the like. The interest lies, not in the general proposition as such, but in how it is handled; here the authors' many well-informed and thought-provoking remarks are marred by a disappointing reluctance to come to the point. W. E. HICK

GEOLOGY AND PALÆONTOLOGY IN MALAYA

Pre-Tertiary Stratigraphic Succession in Malaya

As a result of progress in geological mapping in Malaya since 1939 it has been possible to clarify and to extend considerably the range of known pre-Tertiary stratigraphic units. Formerly, for lack of sufficient palæontological evidence, the sedimentary formations in Malaya were believed by Scrivenor[1,2] and Willbourn[1] to be limited within the late Palæozoic and early Mesozoic eras to the range Carboniferous–Permian–Triassic, and it was thought that, except in the extreme north-western part of the country where arenaceous rocks had been found to underlie calcareous rocks, the formations older than the granite consisted only of one major sequence of characteristically arenaceous rocks of Triassic age and one major sequence of characteristically calcareous rocks of Carboniferous–Permian age. Although some anomalies were observed they were explained by folding, possible unconformity, or the paucity of fossil species, which are too scanty for precise age determinations.

The fact that fossils were so rare in the stratified rocks made it necessary to use lithological characteristics for mapping over large areas. Certain inconsistencies were examined in greater detail by subsequent workers, including Richardson[3], who in 1939 noted in western Pahang that characteristically arenaceous rocks lay structurally immediately beneath characteristically calcareous rocks of Carboniferous–Permian age; and Fitch[4], who in 1940 noted in eastern Pahang that characteristically argillaceous with some calcareous rocks of Lower Carboniferous age lay structurally immediately beneath unfossiliferous arenaceous rocks of presumed Triassic age. Richardson, Service, and Alexander[5] in 1941 recorded their independent beliefs that in western Pahang the unfossiliferous arenaceous rocks which lay structurally immediately beneath the 'Calcareous Series' of Carboniferous–Permian age should not be regarded as Triassic, even though no fossils had been found to prove otherwise. The evidence then available was summarized[6,7] and subsequent work by Alexander[8] between 1947 and 1951 showed that the characteristics of the ultra-stable heavy mineral assemblages of this unfossiliferous arenaceous sequence of western Pahang were not correlative with those of the fossiliferous Triassic rocks found farther east in central Pahang, and added force to the view that this arenaceous sequence is indeed not younger than Carboniferous in age. The status of the proved stratigraphical succession in Malaya by 1951 was then as compiled in 1954 and published in the "International Stratigraphic Lexicon"[9].

In 1952, the Kelantan (Trengganu) Pahang States border area was allocated for systematic detailed mapping. Later, after studying the geological map of Thailand[10], noting certain trans-border anomalies, and doing some preliminary photogeological work, I prepared the ground during November 1954 at the Bangkok meetings of the Economic Commission for Asia and the Far East Working Party of Senior Geologists for the Geological Map of South-East Asia for a detailed stratigraphic correlation survey in the Malaya–Thailand international border areas. Early in 1955 certain parts of Perlis and Kedah were allocated for systematic detailed geological mapping as part of a co-ordinated programme of re-examination of several inconclusive stratigraphic horizons in Malaya, and in 1955–56 the stratigraphic correlation survey in the international border areas[11] was undertaken by a joint party of geologists from Malaya and Thailand.

The results of the work both in the Langkawi Islands and Perlis, and in Trengganu and Kelantan, have been most gratifying and have shown that the

Table 1. Pre-Tertiary Stratigraphic Successions in Malaya and Thailand

Malaya	Age	Thailand
Not yet proved	Late Cretaceous	Not yet proved
Gagau Formation : a predominantly arenaceous sequence not previously differentiated	Early Cretaceous Late Jurassic	Not differentiated
Not yet proved	Early Jurassic	
Lipis Group : a characteristically argillo–arenaceous sequence, formerly known as the 'Younger Arenaceous Series', including an argillo–calcareous formation of late Triassic age; on the West Coast the group is represented by the Semanggol Formation of middle Triassic Age	Triassic	Khorat Series, including the Kamawkala Limestone of late Triassic age
Raub Group : a characteristically calcareous sequence formerly known as the 'Calcareous Series' (the old 'Raub Series')	Permian Late Carboniferous	Rat Buri Limestone
Bentong Group : a characteristically arenaceous sequence formerly known as the 'Older Arenaceous Series', including lenticular cherty formations towards the base of the succession	Carboniferous	Kanchanaburi Series
Kuantan Group : a characteristically argillaceous sequence, not previously named, including lenticular masses of a calcareous formation high in the succession	Early Carboniferous	
Not yet proved	Devonian	No Devonian proved
Setul Formation : a predominantly calcareous sequence not previously differentiated	Silurian Ordovician	Thung Song Limestone
Machinchang Formation : a predominantly argillo–arenaceous sequence, formerly known as 'C_2 beds' and mapped as Carboniferous	Late Cambrian	Phuket Series
Not yet proved	Early Cambrian	

stratigraphic succession in Malaya does indeed range from at least as early as late Cambrian to as late as early Cretaceous, with very little interruption except possibly in the Devonian and in the Jurassic. The positive identification of Ordovician/Silurian fossils found during the course of the Malaya–Thailand border survey in the predominantly calcareous sequence of the Langkawi Islands[12], together with the evidence of structural alignment of the underlying arenaceous rocks with those carrying late Cambrian fossils on the Thai island of Terutau, were critical factors in establishing the identity of the older rocks in Malaya. Such positive fossil evidence has not yet been obtained for the predominantly arenaceous beds overlying granite found in the Kelantan (Trengganu) Pahang border areas, but is sufficient to indicate for them late Jurassic or early Cretaceous age. In the current research programme is included a project for determining the ages of the various granite masses by isotope ratios of radioactive elements in constituent minerals such as zircon, and it is hoped that the results obtained will establish some correlation with the sedimentary indications already found.

In view of the considerable extension of the proved time-range of the Malayan sedimentary succession I decided early in 1958 to give to the various rock groups and formations in Malaya definite names according to type localities in accordance with the recommendations of the International Geological Congress Sub-Commission for Stratigraphic Terminology. Table 1 summarizes the newly adopted nomenclature and the comparative classification of Palæozoic and Mesozoic stratigraphic sequences now established between Malaya and Thailand[13].

This communication is written as a preliminary announcement to a more detailed paper now being prepared in order to bring up to date the stratigraphic descriptions appearing in the first edition of the section on Malaya in the International Stratigraphic Lexicon. The information in this and the two following communications is published with the authority of the Minister of Natural Resources of the Federation of Malaya.

Jurassic/Cretaceous Sediments in Malaya

A FORMATION of gently dipping sedimentary rocks forming the Gunong Gagau plateau was found during a reconnaissance of the Kelantan (Trengganu) Pahang borders in 1952. The succession consists of a coarse basal conglomerate, with cobbles as much as 10 in. in diameter, overlain by a series of progressively finer, interbedded white pebble beds and orthoquartzites, both the latter composed almost entirely of quartz. There are occasional thin red mudstone horizons in which occur plant remains, most of them fragmentary. Recently, better-preserved specimens have been collected which indicate a late Jurassic or early Cretaceous age for the higher part of the formation.

Both in lithology and in the virtual absence of folding and metamorphism these strata appear to be quite unlike any other group of rocks in Malaya, and are the first sedimentary rocks of an age between Trias and Tertiary to have been found. In part they rest with notable unconformity on vertical or steeply dipping interbedded shales, metaquartzites and conglomerates of probable Carboniferous or Permian age. The latter group are characterized by their dark, mainly black, colour arising from the high argillaceous content of the whole succession, and contrast sharply with the light-coloured, overlying beds. Elsewhere, the basal conglomerate overlies granite.

Their discovery throws interesting light on the tectonic history of Malaya. Previously, the folding of sediments and emplacement of granite were thought to be penecontemporaneous and, by analogy with surrounding countries, probably of late Cretaceous or early Tertiary age. However, the present evidence shows that at least a major part of the folding took place early in Jurassic time.

The field-work during the course of which the discoveries were made forms part of the general research programme of the Geological Survey of the Federation of Malaya, and after examination of the area is complete the results will form the subject of a more comprehensive paper.

This preliminary communication is published by permission of the Director of Geological Survey.

Graptolites recorded from Malaya

GEOLOGICAL investigations within the past few years in the north-western States of the Federation of Malaya have resulted in the discovery in 1956 of graptolites in shale bands interbedded with limestone of Ordovician/Silurian age[1] which outcrop along the north-eastern shore-line sections of the Langkawi Islands (6° 25′ N.; 99° 55′ E.). The group of islands lies in the northern funnel of the Straits of Malacca between 20 and 30 miles west of the State of Perlis. Graptolites have been found since in shale associated with limestone in the northern end of the Kinta Valley (4° 46′ N.; 101° 06′ E.) of central Perak. Although the graptolites which have been recovered so far are generally of poor preservation they provide sufficient information to date several horizons with considerable accuracy within the period Caradocian–

Llandovery. Previously, for lack of sufficient palæontological evidence, these formations had been ascribed to the Carboniferous period by conservative lithological comparison with fossil-bearing strata on the mainland of Malaya[2].

It is of more than passing interest to note that the nearest locality to Malaya previously known to provide a graptolitic fauna of Llandovery genera is that at Panghsa-pye (22° 42′ N.; 97° 16′ E.) in the Northern Shan States of Burma as recorded by Holland[3], Chhibber[4], and Krishnan and Jacob[3]. In addition, graptolite-bearing beds of Valentian age have been reported by Sondhi[5] at Wapya Taung (20° 53′ N.; 96° 38′ E.) and at Kwawktap (20° 05′ N.; 96° 46′ E.) in the Southern Shan States. These occurrences all lie more than a thousand miles north of the Langkawi Islands, so that the localities in the Federation of Malaya provide a link between Burma and Australia which will undoubtedly be of great value to palæogeographers in the future.

The field-work during the course of which the discoveries in Malaya were made forms part of a co-ordinated programme of re-examination of several inconclusive stratigraphic horizons, and I am indebted to the Director of Geological Survey, Federation of Malaya, for his guidance and permission to publish this communication.

A RAPID MICRO-QUANTITATIVE METHOD FOR ESTIMATING SERUM CALCIUM

By T. A. HARPER

Group Pathology Laboratory, City General Hospital, Sheffield

An accurate micro-method for estimating serum calcium in children and infants is a necessity in many clinical laboratories. Several micro-methods, using dye solutions, were examined in order to select one for use in this laboratory. The criteria laid down for the method to be adopted were: (1) avoidance of calcium precipitation by oxalate, (2) specificity, (3) accuracy, (4) reproducibility, (5) simplicity, (6) use of available apparatus without any modifications, (7) easily available chemicals, (8) reasonable stability of the reagents as stock solutions. Each of the methods examined had some drawback which precluded its adoption as a routine procedure.

However, the method described by Tammelin and Morgensen[1] satisfied the criteria mentioned earlier. In alkaline solutions murexide–ammonium purpurate is specific for calcium. They made use of the reaction in which the colour of a murexide solution changes from purple to pink on the addition of calcium. Their results showed that it was possible to estimate microgram quantities of calcium in water solutions, even in the presence of magnesium, by means of spectrophotometric determination of the calcium murexide complex. Accordingly, the calcium concentration of 315 samples of serum—obtained from blood donors—was determined to find out the normal range for this method. The purpose of this communication is to present the results obtained and to demonstrate a method for correcting the results to agree with oxalate precipitation methods, as the accepted normal range for serum calcium has been determined by these methods.

The following reagents were used: (1) saturated murexide solution is prepared with distilled water and the solution stored, in a brown bottle, in the + 4° C. refrigerator to decrease the rate of decomposition. A fresh solution need only be prepared after 3–4 weeks. A sufficient volume for the number of tests is centrifuged before use. (2) Piperidine. (3) Stock standard calcium (1 mgm. ≡ 1 ml.). 'Analar' grade of calcium carbonate is dried at 105° C. for 24 hr. 2·5 gm. are weighed and transferred to a 1-l. flask. 200 ml. of distilled water and 50 ml. of normal hydrochloric acid are added. When dissolved, water is added to the mark. (4) Working standard calcium (9 mgm. per 100 ml.) prepared from the stock solution. The apparatus used were a 'Unicam' *S.P.* 600 spectrophotometer and auto self-set zero micropipettes.

Three test tubes are labelled *T* (test serum), *S* (standard calcium solution) and *B* (blank). 4·9 ml. of distilled water is added to tubes *T* and *S* and 5 ml. to tube *B*. 0·1 ml. of the test serum is pipetted into *T* and 0·1 ml. of the working standard calcium solution into *S*. Then one drop of piperidine and 0·25 ml. of the saturated murexide solution (centrifuged before use) are added to each of the three tubes and the contents mixed thoroughly. The optical densities of the three solutions are then read in the spectrophotometer at 500 mμ wave-length using the 0·5-cm. cuvettes, the instrument being set at zero with a water blank.

A permanent standard calibration curve is not possible because, on storage, there is a decrease in the optical density of the saturated murexide solution.

By calculation:

$$\text{Serum calcium} = \frac{\text{Reading of (Test Serum–Blank)}}{\text{Reading of (Ca Std.–Blank)}} \times 9\ \text{mgm./100 ml.}$$

Freeze-dried serum, analysed by the Joint Committee of the Association of Clinical Pathologists and the Association of Clinical Biochemists, was obtained from C. David Keeler, Ltd., and reconstituted. The method was carried out on this serum. The corrected calcium concentration of the

Table 1. SERUM CALCIUM RANGE (MGM. PER 100 ML.)

Author	Method	Lower 1 per cent	Lower 10 per cent	Upper 1 per cent	Upper 10 per cent	Average
Smith *et al.* (ref. 3)	Emission spectrograph	6·08	—	—	10·54	8·6
King and Wootton (ref. 4)	Oxalate precipitation and titration with potassium permanganate	9·0	9·6	10·8	11·4	10·0
Elliott and Pearson (ref. 5)	Oxalate precipitation and spectrophotometric determination with excess potassium permanganate	10·6	—	—	14·6	11·8
Tammelin and Morgensen (ref. 1)	Spectrophotometric determination of calcium murexide complex	7·6	8·0	9·8	10·7	8·9

working standard calcium solution was obtained thus:

$$\frac{\text{Reading of (Ca Std.–Blank)}}{\text{Reading of (Serum Std.–Blank)}} \times \text{Ca conc. of Serum Std. mgm. per 100 ml.}$$

The corrected value of the working standard calcium solution is now used instead of the value 9 for the calculation of the calcium concentration of test sera.

The standard serum is used as the control for the method[2].

The normal serum calcium range varies with the technique employed for its determination (Table 1). It has been found that the murexide techniques give lower results than oxalate precipitation methods[6,7]. This was verified in this series. The range quoted by King and Wootton[4] is the accepted one, and, in order to avoid confusion, the results obtained with murexide techniques must be corrected in order to bring them into agreement with oxalate precipitation methods. Eldjarn, Nygaard and Sveinsson[7] found that the best agreement was obtained when their values were multiplied by a factor of 1·046. The method of correction adopted here is considered to be satisfactory because the subsequent results were in close agreement (± 1 per cent) with those obtained when using the oxalate precipitation method described by King and Wootton[4] and also with various batches of standardized sera which were afterwards used as controls.

The method gives accurate and reproducible results (± 1 per cent), for this has been proved when using the various batches of standardized sera. However, the results obtained with simpler instruments will not be as accurate as those obtained with the spectrophotometer. The method was also tested on two other instruments: (1) the 'Spekker' photoelectric absorptiometer using the Ilford spectrum filter blue-green (603), and (2) the Gallenkamp direct-reading photoelectric colorimeter using the Ilford bright spectrum blue-green filter (623); an optical glass block is inserted into the 1-cm. cuvettes in order to obtain mid-scale readings. The errors with these instruments were ± 2 and ± 3 per cent respectively.

I am indebted to Dr. C. C. Bowley and Dr. J. Darnborough of the Sheffield Regional Blood Transfusion Service Laboratories for the generous supply of sera and to Dr. D. W. Auchinachie, principal biochemist of the City General Hospital, Sheffield, for his advice and encouragement.

EFFECT OF RADIATION ON THE BREAKDOWN OF HOMOGENEOUS FIELD AND SPHERE GAPS

By K. R. ALLEN and DR. K. PHILLIPS

Research Department, Metropolitan-Vickers Electrical Co., Ltd., Trafford Park, Manchester 17

IN the course of some experiments with homogeneous-field electrodes separated by 1 cm. in nitrogen at atmospheric pressure, to which was applied a positive d.c. voltage of 30 kV., it was found that the rate of breakdown increased when the gap was irradiated. Rogowski and Wallraff[1] found that radiation, which would produce a current of 5×10^{-12} amp./cm.^{2} in a spark gap, would reduce the minimum breakdown voltage by about $\frac{1}{2}$ per cent for a gap of 1·5 cm. between spheres at atmospheric pressure.

A quantitative investigation of this effect has been carried out using homogeneous-field electrodes mounted in a glass chamber. The voltage was obtained from a positive high-voltage d.c. source accurately stabilized and controlled by means of a helical potentiometer. After an initial warm-up period, the drift in voltage was found to be approximately 1 part in 5,000 per hr. A 0·001-microfarad condenser was charged through a 100-MΩ resistor, which was in turn connected to one electrode by a 10-MΩ resistor. This arrangement ensured that, when a spark occurred in the chamber, the voltage was chopped and the condenser had to recharge before another spark could occur. The number of discharges per minute was counted for different values of applied voltage for electrode gaps of 1 and 2 cm. at pressures of 76 cm. and 38·8 cm. of mercury in air. The source of radiation was 0·1 mgm. of radium in a nickel pellet situated at (*a*) 30 cm. from

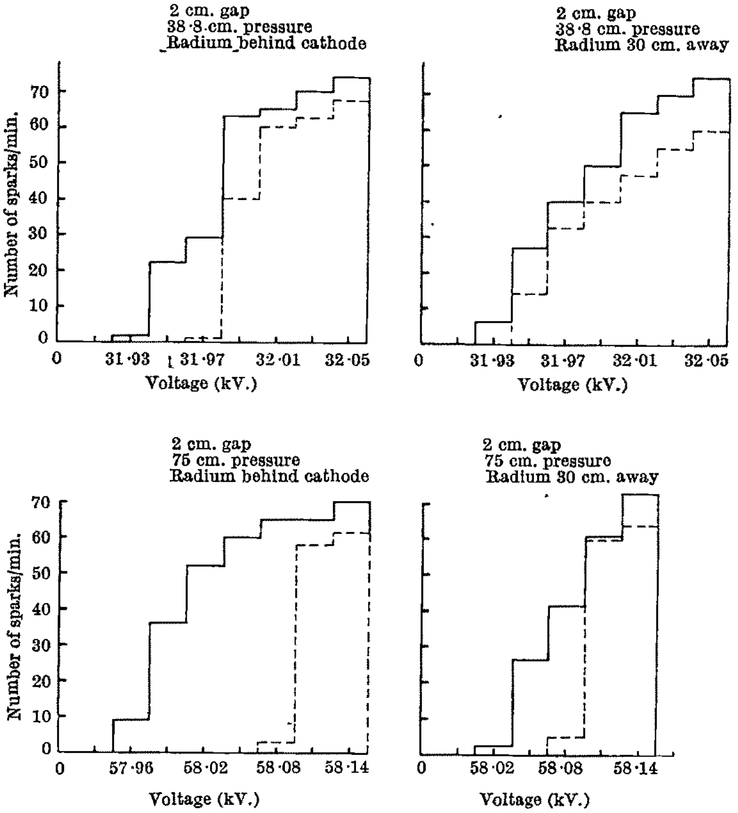

Fig. 1. Histograms showing the variation of the number of sparks/min. with voltage for a 2-cm. homogeneous field gap for different amounts of irradiation and at different air pressures

the gap and (*b*) immediately behind the earth electrode. For each applied voltage, spark counts were taken alternately with and without radiation for 1-min. periods. An example of the results is given in the form of histograms in Fig. 1 for a 2-cm. gap. The dotted histograms give the rate of breakdown without irradiation. In all cases there is an increase in the number of sparks per minute when the gap is irradiated, and there are larger differences between the spark counts as the intensity of irradiation is increased. This increase is more pronounced at atmospheric pressure.

A comparison has also been made between the performance of spheres and plane electrodes, and the results for weak irradiation are shown in Fig. 2. The breakdown voltage of a uniform field gap of 1 cm. was about 2 per cent less than for the same spacing between 5-cm. spheres, and for the experiment the separation of the spheres was reduced to 0·975 cm. so that both gaps broke down at the same voltage. The gaps were connected in parallel and placed so that the radium was 30 cm. from both. The apparent reduction of the breakdown voltage by irradiation was only about 0·1 per cent for the uniform field, but it was about 1 per cent for the spheres. The histogram for the latter also shows that the counting-rate increased relatively slowly with voltage. As a result of this, it is more difficult to determine the minimum breakdown voltage for sphere gaps, and it is necessary to define the intensity of radiation and also the sparking-rate for the minimum breakdown voltage quoted.

The current in the uniform gap when the radium was immediately behind the cathode was about 10^{-11} amp./cm.^{2}, and this would possibly cause some distortion of the field. When the radium was 30 cm. from the gap, the current was several orders of magnitude less, and it seems unlikely that distortion of the field would then occur. The obvious explanation is that irradiation produces more avalanches, resulting in an increased density of positive ions and leading to breakdown when it reaches a critical value. Since the histograms for the irradiated and unirradiated gaps are very similar in shape, it seems reasonable to assume that the breakdown mechanism is the same in both cases, and depends on the successive growth of avalanches across the gap. This is effectively the Townsend mechanism of multiple-avalanche production, but without necessarily having recourse to a γ-mechanism. Evidence in support of this explanation is afforded by observations of avalanche growth in a cloud chamber. Here it was found that 'curtains' of avalanches originated from the ionization produced by an electron track within the gap. If several such curtains are formed in a time less than that required for positive ions to diffuse out of the gap, then the density of positive ions will build up rapidly. The density of positive charge is a significant factor and explains why the irradiation has less effect at lower pressures.

If one considers the field distribution across a sphere gap, the effect on α is to reduce its value in the mid-gap region. Consequently, avalanches beginning to grow from the cathode may not reach the anode if α falls to a low value. On the other hand,

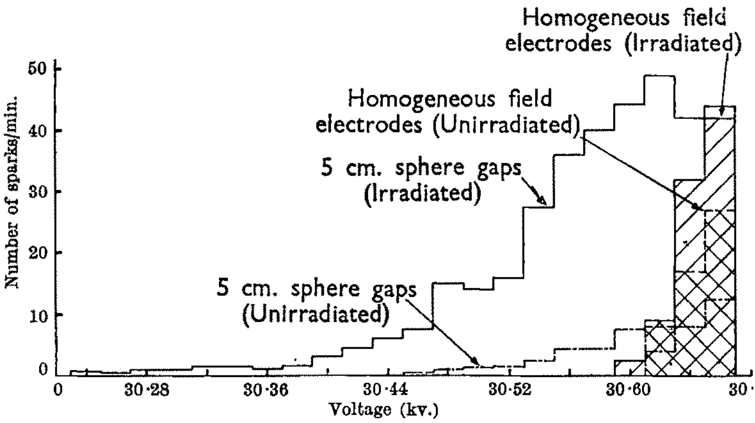

Fig. 2. Comparison between the number of sparks/min. for homogeneous field and sphere gaps of 5 cm. diameter. 1 cm. homogeneous field gap and 0·975 cm. sphere gap. 76 cm. pressure. Radium 30 cm. away.

mid-gap avalanches will grow to the anode in a region of increasing field. If the value of αd is calculated for an avalanche crossing half the non-uniform field gap of 1 cm. between spheres of 5 cm. radius, it is found that the value of X/p required to give equal values of αd is several per cent greater for the spheres. This effect is connected with the phenomenon known as the Toepler[2] discontinuity, and has been studied in detail by Claussnitzer[3].

The relatively slow increase in counting-rate with voltage for sphere gaps can be explained as follows. The value of α across a uniform field is constant, whereas in a sphere gap α has a greater value near the electrodes than in the middle. Therefore, as X/p is reduced in the first case, α rapidly changes from a value which is sufficient to maintain ionization growth to a value which cannot support such growth. In the second case, as X/p is reduced, there is a larger range in which α is sufficient to produce ionization growth. It has been observed that the slope of the counting-rate curve is affected by the presence of water-vapour; results will be reported later. No correction has been made for the effect of humidity, but since the measurements are relative such a correction was considered unnecessary.

The greater effect of irradiation in the case of spheres can be explained as being a volume effect. The average ionization produced by natural causes is about 10 electrons/c.c./sec. In a sphere gap the effective volume for avalanche growth is small; hence any artificial sources of radiation will add to the low value already existing, whereas the uniform field can be assumed to be sufficiently irradiated by natural sources. Here again the fact that α varies across the gap explains why the voltage can be reduced further with irradiation in a sphere gap than in a uniform field. If the voltage is reduced by a small amount and α drops to less than a minimum value, no reasonable amount of irradiation will cause the uniform-field gap to break down.

HEPARIN AND THROMBOPLASTIN GENERATION IN THE HORSE

By Dr. R. K. ARCHER

Equine Research Station of the Animal Health Trust, Newmarket

AND

P. FLUTE

Department of Medicine, Cambridge

A SERIES of experimental ponies were injected intravenously with 250 I.U. per kilogram of heparin ('Liquemin'; Roche) and a number of observations made on these animals. The horse has at least one appreciable experimental advantage, in that it is possible to remove relatively large volumes of blood at frequent intervals without materially affecting the physiological *status quo*. The purpose of this communication is to enlarge upon a thromboplastin generation defect which was observed.

The expected prolongation of clotting time in glass tubes at 37° C. was accompanied by prolongation of the one-stage plasma prothrombin time, using either horse brain thromboplastin or Russell's viper venom. There was a concurrent defect in thromboplastin generation. With the exception of the test using Russell's viper venom all these abnormalities extended over a period of five hours after the injection (Fig. 1).

Thromboplastin generation tests were performed according to the method of Biggs and Douglas[1], modified by replacing platelets by a chloroform extract of acetone-dried horse brain[2], and using only horse blood in the preparation of the solutions. Alumina plasma was prepared from high-spun citrated plasma with a very low platelet content. A typical series of results is shown in Fig. 2. In the preparation of each curve alumina plasma, serum and substrate plasma were each derived from the appropriate blood specimen. The experiments were performed upon six ponies.

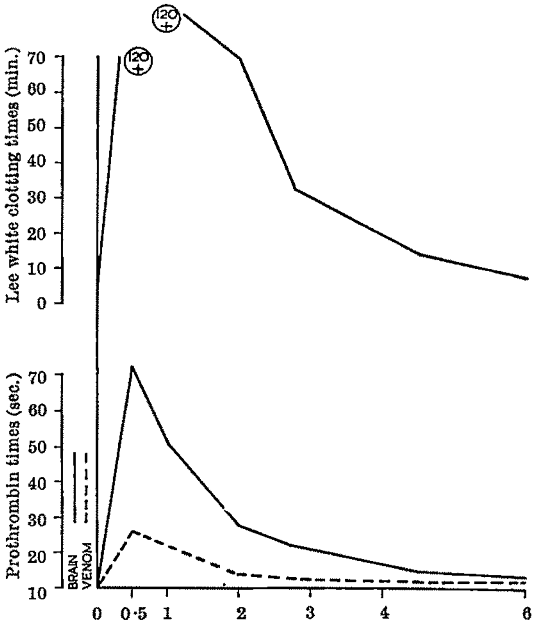

Fig. 1. The effect of intravenous heparin in the horse upon whole blood clotting time; and the 1-stage prothrombin time using either brain extract or Russell's viper venom as the thromboplastic source

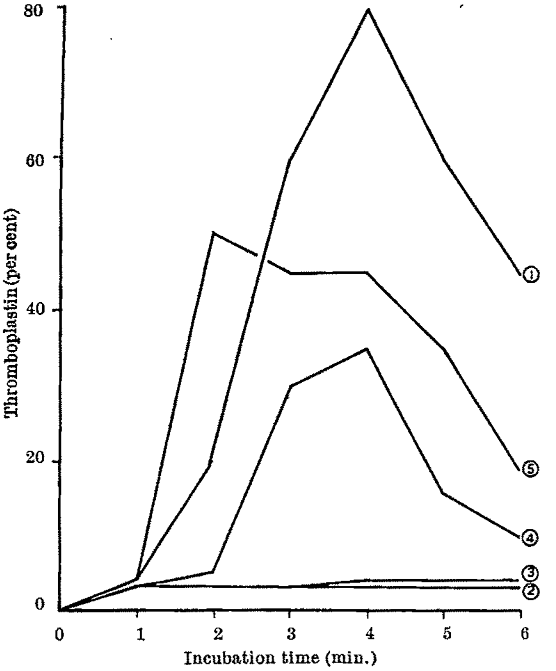

Fig. 2. Thromboplastin generation in the horse after intravenous heparin. (1) Before injection; (2) ½ hr.; (3) 1 hr.; (4) 2 hr.; (5) 4 hr. after injection

It was possible to demonstrate that plasma taken 2 hr. or more after the injection of heparin reacted equally as well as normal horse plasma when used as substrate in the test. The persistent defect in curves 4 and 5 therefore represents a failure of thromboplastin generation rather than a failure to react with formed thromboplastin. Subsequent attempts to define the nature of this defect were confined to specimens taken at 2 hr. or afterwards.

Substitution of either normal alumina plasma or normal serum in a system otherwise derived from the 2-hr. post-injection specimen gave an increase in thromboplastin formation in each case, though this was usually greater when normal serum was used. Thus a defect in both alumina plasma and serum activity was detected.

The addition of 0·1 ml. of saline, or saline containing other reagents at various dilutions, to a system wholly derived from the 2-hr. post-injection specimen was next investigated. Complete correction could not be achieved. Normal horse alumina plasma corrected the deficiency to 60 per cent of normal at an optimal original dilution of 1 : 5; normal serum corrected to 70 per cent at 1 : 10 original dilution; a preparation of Christmas factor from horse serum[3], shown to be as active as normal human serum in replacing the defect in a human subject with severe Christmas disease, gave only 40 per cent correction at a 1 : 20 original dilution. Normal horse serum previously adsorbed with a suspension of aluminium hydroxide gave the best overall correction, usually 80 per cent at a 1 : 10 original dilution.

These results in the horse differ from those reported in humans. Following the injection of heparin into human volunteers, O'Brien[4] has described a deficiency in thromboplastin generation corrected by normal serum but not by Christmas disease serum or by alumina-adsorbed serum. Normal alumina-adsorbed human serum and alumina-adsorbed serum from a case of severe Christmas disease were as effective as horse alumina serum in the correction of the defect in the horse.

Conversely, in one experiment, plasma from the 2- and 4-hr. experiments was equally as active as normal horse plasma in replacing the deficiency in the plasma of a human subject with classical hæmophilia (hæmophilia *A*). The 2-hr. specimen had only 25 per cent, and the 4-hr. 45 per cent, of the ability of normal horse blood to replace the deficiency of a human subject with Christmas disease (hæmophilia *B*).

Using Russell's viper venom as a source of thromboplastin the one-stage times of the 2- and 4-hr. plasma specimens were normal, though the defect seen using horse brain thromboplastin still persisted. This suggests that the latter may be accounted for by a deficiency of factor VII[5].

It has been demonstrated[6-8] that the horse coagulation system resembles that of humans in many respects. Since the defect in thromboplastin generation produced by heparin is corrected by alumina adsorbed serum, a deficiency of factors thought to be present in adsorbed human serum must be considered.

Factor X and Stuart-Prower factor, which may be identical[9], are associated in man with a deficiency of both thromboplastin generation and the one-stage prothrombin time using Russell's viper venom[10]. These may be present in alumina serum, but as the Russell's viper venom time has been shown to be normal while thromboplastin generation remains deficient, they are unlikely to give rise to the defect described here.

Human plasma exposed to contact with glass shows accelerated clot formation[11]. Failure to react normally to contact with glass, together with failure of thromboplastin generation, is seen in humans deficient in either Hageman factor or plasma thromboplastin antecedent[12]. Both these factors are known to be present in alumina-adsorbed serum as well as in serum and in alumina-plasma. Glass contact has been shown to activate factor VII and Christmas factor[13], and human cases deficient in plasma thromboplastin antecedent behave as if they have a deficiency of Christmas factor activity[12].

If a similar reaction to contact with glass, dependent upon factors with similar properties, exists in the horse then the findings after heparin injection might be interpreted as a failure to react normally to contact with glass. Further investigations of the ability of normal horse plasma to react to contact with glass is necessary before these observations can be fully interpreted.

REDUCTION IN THE LETHAL EFFECTS OF RADIATIONS ON *ESCHERICHIA COLI B* BY TREATMENT WITH CHLORAMPHENICOL

By Dr. N. E. GILLIES and TIKVAH ALPER

Medical Research Council Experimental Radiopathology Research Unit,
Hammersmith Hospital, London, W.12

MANY procedures have been reported for bringing about 'recovery' in *Escherichia coli B* after irradiation. Alper and Gillies[1] found that the observed sensitivity of this strain to both ultra-violet and ionizing radiations was very dependent on methods of culture, and that survival of the irradiated bacteria was least in those conditions in which the non-irradiated bacteria grew fastest. This suggested that inhibition of some metabolic step, for a limited period after irradiation, might lead to increased survival of the irradiated bacteria. Since chloramphenicol has been reported to inhibit protein synthesis[2], its effect on irradiated cells of *E. coli B* has been investigated. It has been found that the lethal effects of both X-rays and ultra-violet light are greatly reduced if the bacteria are incubated for a period after irradiation on solid medium containing chloramphenicol (5 μgm./ml.). We believe that no post-irradiation treatment reported hitherto has been as effective in reducing the observed sensitivity to X-rays.

Survival of the bacteria was determined by counting colonies which grew on 'Cellophane' carriers lying on the surface of nutrient agar ('Oxoid' blood agar base). The use of these carriers throughout the experiments permitted rapid transfer of irradiated or control cells from one medium to another, so that they could be removed from contact with the chloramphenicol without the necessity for washing and centrifuging. The methods of preparing bacterial suspensions for irradiation, and of dispensing aliquots on to the 'Cellophane' carriers, have been previously described[1]. Ultra-violet irradiations were carried out with the bacteria spread on pieces of 'Cellophane' lying on the surface of agar gel containing no nutrients. In the X-ray experiments the bacteria were irradiated in liquid suspension, in the presence and absence of oxygen, by methods which ensured control of the dissolved gases[3]. Transfers to nutrient medium, with or without chloramphenicol, were made as soon as possible after irradiation, and all plates were warmed to 37° before transfer. Colony counts were made after a final incubation period of at least 15 hr. on nutrient medium, and treatments of irradiated bacteria were always matched by the same treatment of controls, which were found to yield a constant count irrespective of the length or timing of the incubation period on chloramphenicol–agar.

The X-ray experiments were carried out on stationary-phase suspensions only. Dependence of the surviving fraction on the period of incubation on chloramphenicol–agar is illustrated by Fig. 1. With no chloramphenicol treatment, a dose of 19 kilorads delivered in anoxic conditions reduced the population to the same fraction as a dose of 9·9 kilorads delivered under oxygenation. It may be seen that the 'rescue' by chloramphenicol treatment was considerably greater after irradiation in anoxic conditions. Incubation for 3 hr. on chloramphenicol–agar immediately after irradiation increased the surviving fraction by a factor which corresponded to a twofold reduction in the effectiveness of the X-rays delivered in the presence of oxygen, and a fourfold reduction in anoxic conditions. The factor by which oxygen was observed to enhance the effect of radiation was only about two, if surviving fractions were compared when the bacteria were placed immediately on nutrient agar. This ratio was roughly doubled, however, if the observations were made on surviving fractions after 3 hr. of chloramphenicol treat-

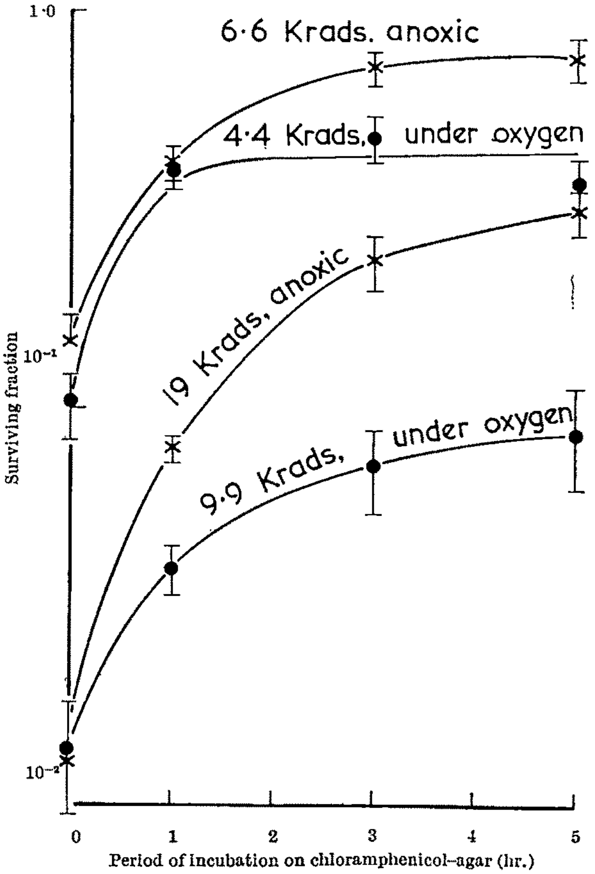

Fig. 1. Dependence of surviving fraction of X-irradiated *E. coli B* (stationary phase) on period of incubation on chloramphenicol–agar

ment. These results confirm our previous report[4] that the enhancing action of oxygen is exerted mainly on a fraction of the damage not affected by post-irradiation conditions. When these are of a nature to reduce overall sensitivity, the observed effect of oxygen is increased.

The dependence of surviving fraction on the period of incubation on chloramphenicol-agar, after ultra-violet irradiation at 2537 A., followed roughly the same course as that illustrated in Fig. 1, when stationary phase bacteria were used. An interesting difference was observed, however, when bacteria in the logarithmic phase were exposed to ultra-violet light. As shown in Fig. 2, short periods on chloramphenicol led to a decrease in the number of colonies formed by bacteria irradiated in the logarithmic phase. This suggests that the initial inhibitory action of chloramphenicol enhances the effect of the radiation, and that a secondary, and more complete, inhibition of metabolism enables many of the cells to proceed successfully to division, after they have been removed from the chloramphenicol.

Survival of both ultra-violet- and X-irradiated bacteria could be still further increased if the irradiation was followed by a preliminary period (up to 1 hr.) on nutrient agar, before commencement of the chloramphenicol treatment. This was found to eliminate the initial decrease in surviving fraction observed with logarithmic phase bacteria. The effects of preliminary incubation on nutrient agar combined with varying periods of chloramphenicol treatment are illustrated in Fig. 3. It can be seen that after a dose of ultra-violet light which reduced the surviving fraction of untreated bacteria to 8×10^{-3}, samples which were incubated for 1 hr. on nutrient agar, then for 2 hr. on the medium containing chloramphenicol, and finally overnight on nutrient medium, formed as many colonies as the control unirradiated suspension. Thus virtually all the effect of this dose of ultra-violet light appears to be due to a metabolic disturbance, the effects of which may be counteracted by the inhibitory action of the chloramphenicol. When stationary-phase bacteria were used, chloramphenicol treatment applied in the same way increased the surviving fraction from 4×10^{-3} to 0·85. In a comparable experiment with X-rays delivered in anoxic conditions, the surviving fraction increased from $7{\cdot}3 \times 10^{-3}$, for bacteria plated on nutrient agar, to about 0·55, after chloramphenicol treatment following 1 hr. preliminary incubation on nutrient medium. Thus a smaller fraction of the overall effect of X-rays is attributable to the metabolic disturbance which is mainly responsible for the lethal effect of ultra-violet light on *E. coli B*.

ASTRONOMY and ASTROPHYSICS

Volcanoes on the Moon

For some time, opinion on the origin of the Moon's craters has been hardening in favour of the meteoric theory and against the volcanic. The recent observation of volcanic activity by Dr. Kozyrev has, in some quarters, produced a reaction in favour of the volcanic origin. I would like to suggest that this reaction is unnecessary.

Whatever is the origin of the craters it is possible that they may be filled with dust to considerable depths. The thermal conductivity of dust, in a good vacuum, and under a low gravitational pull, is likely to be extremely low, owing to the small areas of actual contact between the particles. It may be supposed that this area of true contact between adjacent particles depends only on the force between the two particles and on the yield-strength of the material composing them. In a thick layer of dust, the force between particles of given size will increase linearly with depth from the surface and hence so will the area of true contact. Suppose the mean density is ρ gm. cm.$^{-3}$. Then at depth h cm. the pressure is ρgh dynes/sq.cm. If the compressive yield-strength of the material is s dynes/sq.cm., the contact-areas in each column of particles will be only $\rho gh/s$ of the cross-sectional area of the column.

The effect of this on the conductivity will depend on the shapes of the particles before deformation. If we use the drastic simplification of supposing the particle contacts to be derived from pyramidal points crushed on to plane surfaces, we find that the effective conductivity k_e is given approximately by $2k\sqrt{\rho gh/s}$ when the quantity $\rho gh/s$ is small, k being the thermal conductivity of the solid material. If we suppose the material forming the dust to be a fairly hard rock (Mohs' scale 6 or Vickers' hardness 700 kgm./mm.^{2}) with thermal conductivity 5×10^{-3} cal. cm.$^{-1}$ deg. C.$^{-1}$, and take g to be 160 cm. sec.$^{-2}$, this gives a value of k_e of about $7 \times 10^{-7}\sqrt{h}$. At 100 m. in the case considered, the conductivity might be around 1/70 of the bulk value or, at 1 m., 1/700 of the bulk value. Owing to the multiplicity of reflecting surfaces, the contribution of radiation can be neglected, and gas conduction, important in more familiar circumstances, is zero.

In such conditions the importance of the Moon's natural radioactivity may be high, although, owing to the Moon's small size, it has usually been thought less important than that of the Earth. Suppose that this is equivalent to 2 parts per million of uranium—appreciably less than the equivalent total activity of the Earth's crust. An isolated piece of such material will then show a temperature rise in the region of 8 deg. C. per million years. Since the conductivity of hot rock is fairly high, the interior of the Moon is likely to have reached an equilibrium temperature some time ago. In equilibrium conditions the heat flux reaching the surface must be the whole of that produced in the interior. This will give about 260 calories per year per cm.^{2} or $8{\cdot}4 \times 10^{-6}$ cal./sec./cm.^{2}. Then if T is the difference between the temperature at depth h and the mean surface temperature:

$$\delta T = \frac{8{\cdot}4 \times 10^{-6}\ \delta h}{7 \times 10^{-7}\sqrt{h}} \text{ deg. C.}$$

$$\text{so } T = 24\sqrt{h} \text{ deg. C.}$$

At 1-m. depth this is already 240° C. It will reach the softening point of, for example, basalt at about 25 m. depth if we neglect changes in properties with temperature. In other words, dust could not lie indefinitely over large areas to depths of more than about 25 m. With a thickness of only a few metres, conduction to the sides of a crater kilometres across will be as important as conduction through the dust. Even if the craters were not formed by volcanic action, however, the mere filling of the larger ones with dust would provide, in time, for volcanic activity in the centres.

It is unlikely that enough material would be involved in any one eruption to cause the ejection of major quantities of liquid or solid. The very low mechanical pressure of the dust would seem rather to encourage frequent small local instabilities due to high-temperature release of gases. These instabilities would result in periodic liberation of puffs of hot gas and dust just as the slow liberation of marsh gas leads to occasional bursts of mud and gas from the bottom of a stagnant pond. 'Frequent' here means many times per million years. The phenomenon would therefore appear analogous to boiling with bumping rather than to volcanic action on the Earth's surface, and would produce just the kind of phenomenon which has been observed. It is not so likely that it could be responsible for the central peaks which are often observed in the larger craters.

I am indebted to Mr. F. R. Stewart of this Department for pointing out that, if this picture of events is even approximately true, a large and fairly accessible source of power should be available to the establishments which will doubtless be set up on the Moon in due course.

Changes in the Inclination of Satellite Orbits to the Equator

In a recent article[1], we gave some details of changes in the orbital inclination of *Sputnik* 2 (1957β) and suggested that these changes might be caused by the rotation of the atmosphere. Bosanquet has presented an analysis[2] which supports this view, giving fair agreement with the observed changes. We have now completed a more thorough investigation, taking into account the spread of atmospheric resistance around perigee.

If the atmosphere is assumed to rotate with the same angular velocity as the Earth, and the drag force acts along the direction of motion of the satellite relative to the air, the change, Δi, in orbital inclination i is given by:

$$\Delta i = \Delta T \cdot \frac{\sin i}{6} \cdot \frac{(2I_2 - 4e\,I_1)\cos^2\omega + I_0 - I_2 + 0(e^2)}{(1 - T\cos i)\,I_0 + 2e\,I_1} \quad (1)$$

where T is the period of revolution expressed as a fraction of a day, e is the eccentricity of the orbit, ω is the argument of perigee, I_n is the Bessel function of the first kind and imaginary argument of order n and of argument ae/H, where a is the semi-major axis of the orbit and H is the scale-height of the atmosphere.

It will be noted that Δi is related directly to changes in period ΔT, so that irregularities in air density do not affect the analysis. Also, with $0 < i < 180°$, the inclination i always decreases, so that for a satellite moving from west to east $(0 < i < 90°)$ the maximum latitude decreases—this corresponds to the condition for all satellites launched to date—whereas for a satellite moving from east to west $(90° < i < 180°)$ the maximum latitude increases.

If the Bessel functions are replaced by their asymptotic expansions, equation (1) reduces to:

$$\Delta i = \Delta T \cdot \frac{\sin i}{3} \frac{(1 - 15k/8 - 2e)\ \cos^2\omega + k}{(1 - T\cos i)\,(1 + k/8) + 2e} \times \{1 + 0\,(k^2, e^2\}, \ldots \quad (2)$$

where $k = H/ae$. This expansion is most appropriate, since k and e are of the same order if $0{\cdot}05 < e < 0{\cdot}15$.

Equation (2) shows that the change in i depends mainly on three quantities: (1) i itself—the greater the inclination the greater is the change, because the force due to the rotating atmosphere is more nearly perpendicular to the path; (2) the change in period, ΔT, which is a measure of how much the atmosphere is affecting the orbit in general; (3) the angle ω from equator to perigee, the effect being greatest when perigee is at the equator, where the rotational speed is greatest.

If, in equation (2), the terms in k, e, T are ignored, the equation given by Bosanquet[2] is obtained. For *Sputnik* 2 it is found that the change in inclination obtained from (2) is about 30 per cent less than that given by the simpler equation, and this scarcely justifies the use of the latter.

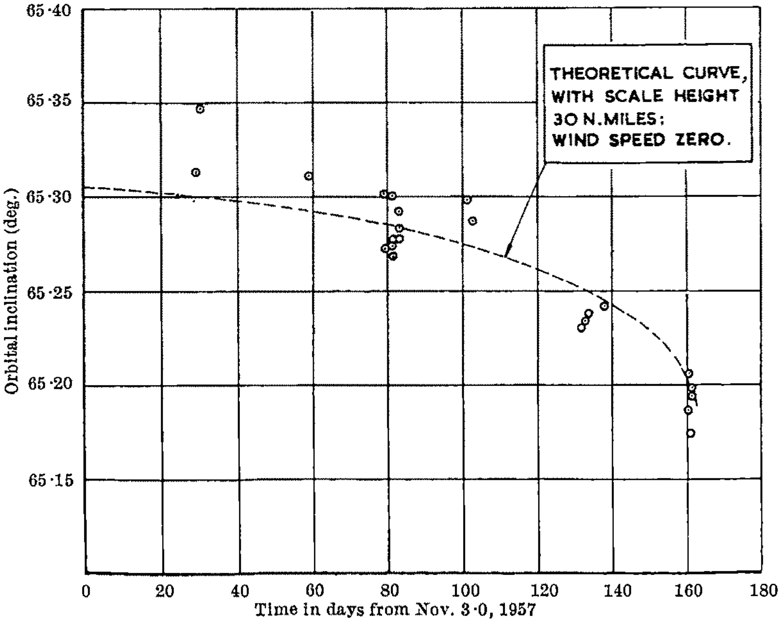

Fig. 1. Mean orbital inclination of *Sputnik* 2 (1957β)

The theoretical curve for the inclination of *Sputnik* 2, obtained by numerical integration of equation (1), is compared with the observed values in Fig. 1. It appears that the theoretical curve is not quite steep enough. Analysis of observations of the rocket of *Sputnik* 3 (1958δ1) is not yet complete, but a decrease in inclination is apparent, and again the theoretical curve is not steep enough. Its slope would, however, be increased if there were a strong wind from west to east. It is indeed possible, in principle, to determine mean wind speed at height of perigee by measuring the changes in orbital inclination; but this would require more accurate observations than are at present available and a theory which took account of other effects such as the oblateness of the atmosphere. The most that can be said now is that rotation of the atmosphere is responsible for the major part of the observed effect.

'Turbulence' and the Photospheric Granulation

EARLY high-resolution photographs of the solar photosphere showed a well-defined pattern of bright granules with diameters lying mostly in the range 1–2 sec. of arc. The similarity of this structure to laboratory convection patterns led to the view that the granules represent convective cells of the Bénard type. However, although some modern observers[1–3] apparently confirmed the existence of a granular structure with the same narrow distribution of sizes, others reached contrary conclusions. In particular, on the basis of photometric measurements of photographs obtained at Mt. Wilson, some workers[4–6] have concluded that the solar surface actually presents the appearance of random brightness fluctuations. These brightness fluctuations have been identified with so-called 'turbulent eddies'. In fact, the view is now widely held that the photosphere is in a state of aerodynamic turbulence. (This conclusion has been opposed by Plaskett[7].) This interpretation, however, does not accord with results derived from sequences of high-quality photographs of the granulation obtained recently by Leighton[8] in the United States and by us[9] in Australia. These cinematographic observations strongly support the convective interpretation and argue against the existence of turbulence.

Both sets of observations show the granules as bright features of various shapes, 1–2 sec. of arc in diameter, which are separated by darker material. The appearance of individual granules persists in detail from photograph to photograph over periods of several minutes. A photograph of superb quality recently published by Rogerson[10] shows a similar pattern: although there are a few features of diameter less than 0·5 sec., the majority of the granules appear to have diameters in the range 1–2 sec. (The dark boundaries appear narrower than on photographs of lesser quality.) These photographs all strongly suggest that the granules are to be identified with convection cells and not with the 'eddies' of any large-scale turbulence.

In addition, the Australian observations support Leighton's hypothesis that the motions within the granules themselves are non-turbulent. The observations are of sufficient quality to enable the development of individual granules (classified according to brightness, size, and shape) to be followed from photograph to photograph over an average period of nearly 7 min. The 125 granules selected for study displayed remarkable stability: 57 per cent showed no detectable change in brightness, size, or shape over this period, an additional 14 per cent showing only minor changes of shape. This stability argues strongly against the existence of aerodynamic turbulence within the granules. The observations are based on photographs contained in a 10-min. sequence, the variable quality of which limited the period over which it was possible to study changes[9]. A longer sequence of better photographs might well show that the stability persists over even longer periods.

Many workers have deduced the existence of 'turbulent' velocities of the order of 2–3 km./sec. from measurements of line profiles and equivalent widths (cf. Waddell[11]). However, these velocities should be regarded as mere parameters indicating the existence of non-thermal motions[12]: they provide no evidence for fully developed turbulence in the strict aerodynamic sense[13]. Moreover, spectroscopic measurements refer to a region of the photosphere lying above the granulation observed in white light; in this region the vertical convection currents may be modified by the onset of radiative cooling (cf. Plaskett[14]).

The available observational evidence thus argues against the existence of turbulence in the photosphere. How far is this conclusion consistent with the known properties of turbulence in gases? It has often been contended that, in view of the high value of the Reynolds number, the solar gases must be turbulent. However, the Reynolds number criterion for the onset of turbulence is an empirical rule, valid in the case of the forced flow of an incompressible fluid through a pipe, but not necessarily applicable to the photosphere. Moreover, turbulence requires for its maintenance a continuous source of mechanical energy[15,16]. In the photosphere the only possible source is the convective motion, which arises from thermal instability. However, if turbulence were present, the consequent transfer of momentum between the upward- and downward-moving columns would tend to destroy the motion, so that the turbulence would be self-damping.

Richardson and Schwarzschild[17], by an erroneous application of Kolmogoroff's law, have even gone to the extent of deriving a complete 'spectrum of turbulence' for the photosphere (cf. Burgers and Thomas[18]). According to Richardson and Schwarzschild the most energetic 'turbulent elements' have a diameter of about150 km. (ref. 17) or 300 km. (ref. 19) (0·2 or 0·4 sec. of arc); these are identified by them with small, very bright granules—so far unobserved. Our observations are not capable of showing structures as small as this. However, they reveal no correlation between the brightness and size of individual granules: in fact, it is found that bright granules are just as likely to be larger as smaller than average.

PHYSICAL SCIENCES

Emission of Slow Secondary Electrons

In a recent paper[1] measurements of the probabilities of multiple emissions of secondary electrons are reported. These indicate that emission of at least some secondary electrons depends on interaction between the primary electron and the solid plasma as a whole, the co-operative interaction[2] as opposed to the individual interaction of current theories[3].

The main points to be explained are: (1) the existence of a group of slow secondaries in a continuous energy-range about 1 eV., nearly independent of the material and of bombardment conditions; (2) the emission of secondaries within 2×10^{-10} sec. following the primary impact[4]; (3) the steep rise of the secondary emission coefficient to a maximum at a primary energy of about 200 eV. followed by a slow fall as primary energy is increased[5]. These facts are consistent with a process for which the classical analogue is the fall of a drop into a body of liquid. As is well known, the reaction of the liquid forces a globule on a narrow neck well above the free surface of the liquid.

In secondary emission, injection of a primary across the boundary will result in transient motions of the negative charge cloud such that a high local negative charge density forms about the point of entry after a time of the order of the period of the plasma oscillation (about 10^{-15} sec.). The rise of this density forces electrons successively over the work-function barrier and accelerates them only slightly after ejection. Such secondaries will be instantaneous to a degree beyond experimental requirements, nearly independent of the detailed properties of the primary, of low emission velocity since acceleration after emission is due at most to a few electron charges. Emission energies will cover a continuous range since acceleration will depend on the rate of build-up of surface charge after ejection, that is, on the phase of the plasma cycle at ejection.

At low primary velocities little energy will be transferred to the plasma since the charge cloud can adjust itself to equilibrium with the moving charge at all stages. Maximum energy will be transferred when the primary electron travels one interaction distance within the plasma in a time of the order of the plasma cycle. Above this velocity energy transfer will fall slowly. Quantum mechanical description of the process is likely to be difficult.

Changes in Transition Probability due to the Interaction of Rotation and Vibration in Diatomic Band Spectra

THE distributions of rotational and vibrational intensities in band spectra are frequently used for measurement of effective temperatures in, for example, flames[1] and stellar spectra. In such calculations it has become customary to treat independently the derivation of rotational and vibrational transition probabilities, although the possibility of error has been noted[2,3]. Major errors attributed to an interaction occur with the weak (0, 1) band of OH at 3428 A. as shown by the incompatible rotational 'temperatures' obtained from a plot such as Fig. 1, calculated on the assumption that only rotational transition probability affects intensity within a band. The gradients of the three straight lines correspond to temperatures of 2,290, 1,420 and 750° K. for R, Q and P_1 branches respectively. The curved portions at low energies are due to unresolved satellite branches. Similar treatment of a stoichiometric flame, using the intensities of Bass and Broida[4], give for the (0,1) band R branches a temperature of 4,180° K., and for the P branches 1,380° K.; even the S branch of the (0,0) band at 3064 A. gives 3,560° K. The estimated temperature of the flame was 2,750° K. Further discrepancies for other bands of the system have been reported[5]. The (0,1) band is very weak, and these effects cannot be attributed to self-absorption.

Rotational transition probabilities are derived from statistical considerations. Vibrational ones are based on the Franck–Condon principle and are derived by calculating the overlap integrals of the vibrational wave-functions; they thus depend on the forms of the two potential energy-curves. When rotation is taken into account the potential curves are modified by adding a term in $J(J + 1)/r^2$. Fig. 2 shows curves for the rotational levels $J = 1\frac{1}{2}$ and $J = 20\frac{1}{2}$, and it is seen that the minima are displaced to larger internuclear distances, especially for the upper, $^2\Sigma^+$, state. This displacement modifies the overlap integrals.

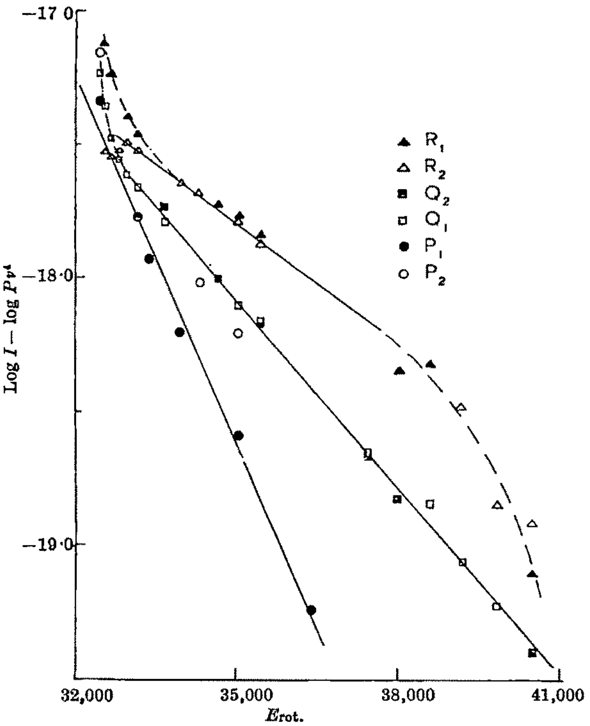

Fig. 1. The (0,1) band of OH at 3428 A. Log $I/P\nu^4$ plotted against the energy of the rotational level from which a transition, intensity I, frequency ν, originated. Source: a hydrogen-rich H_2/O_2 flame at atmospheric pressure, photographed on a large quartz spectrograph of dispersion 4 A. per mm.

We have made calculations of these overlap integrals using wave functions for a Morse–Pekeris oscillator, including rotation[6], and obtain the following transition probabilities:

(0,0) band	P_1 (1)	1·00	P_1 (20)	0·96
	Q_1 (1)	1·00	Q_1 (20)	0·94
	R_1 (1)	1·00	R_1 (20)	0·91
(0,1) band	P_1 (1)	0·11	P_1 (20)	0·12
	Q_1 (1)	0·11	Q_1 (20)	0·15
	R_1 (1)	0·11	R_1 (20)	0·17

Assuming[7] that the electronic transition moment is proportional to e^{-3r} these become:

(0,0) band	P_1 (1)	1·01	P_1 (20)	0·74
	Q_1 (1)	1·00	Q_1 (20)	0·71
	R_1 (1)	0·99	R_1 (20)	0·67
(0,1) band	P_1 (1)	$0{\cdot}01_6$	P_1 (20)	$0{\cdot}01_5$
	Q_1 (1)	$0{\cdot}01_7$	Q_1 (20)	$0{\cdot}02_3$
	R_1 (1)	$0{\cdot}01_8$	R_1 (20)	$0{\cdot}03_5$

It will be seen that for the (0,0) band the changes of vibrational transition with rotational quantum number or branch type are relatively small but, assuming a linear relationship, the change of slope would still cause a difference in temperature of 300° at 3,000° K. For cases such as the (0,1) band where the overlap integral is very small the effect of rotation and of branch type becomes really important.

The results for the (0,1) band are extremely sensitive to the difference $(r_e' - r_e'')$, a change of 0·1 per cent in either r_e causing a change of 10 per cent in the transition probability; the accuracy is

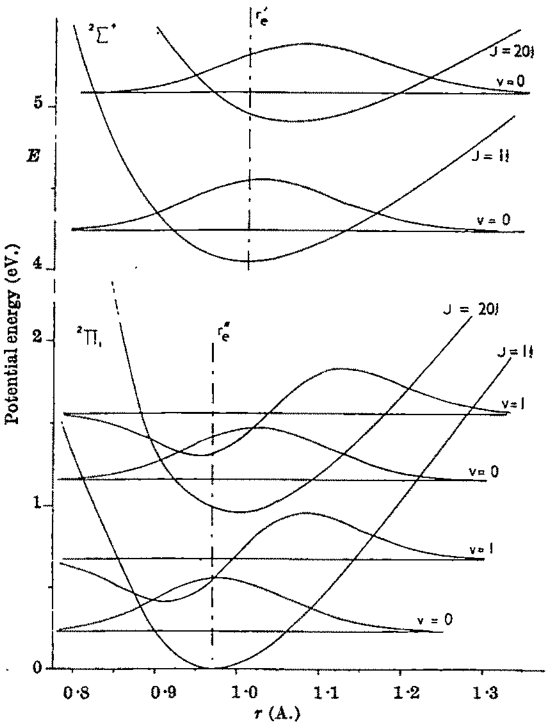

Fig. 2. Graphs of potential functions and wave functions for $A^2\Sigma$ and $X^2\Pi$ of OH

further limited by the result appearing as the difference between two relatively large quantities. The (0,0) band does not suffer from either of these defects and is therefore considerably more accurate.

We are indebted to Dr. R. C. Herman for helpful discussion.

We intend to investigate this problem in greater detail in the near future, using electronic computation to carry out the large quantities of arithmetic involved.

Hollow-Cathode Emission of the AlO Spectrum

All emission bands previously attributed to the AlO molecule have been observed in the glow from a hollow cathode containing $Al–Al_2O_3$ pellets. The hollow cathode is a much more appropriate source for high-resolution studies than is the aluminium arc, and it is therefore gratifying that it may be used to excite materials as refractory as this one. Our discharge tube is quite similar to that described by Naudé and Hugo[1] except that currents as high as 2 amp. were used. It has been employed with a 150,000-line Bausch and Lomb plane grating to record the green (A—X) bands of AlO in third order at a dispersion of 0·4 A./mm. and the ultra-violet bands in second and third orders. Effective resolving powers up to 200,000 have been achieved.

Fig. 1 shows a section of the (0—0) band of the A—X system, near the head. The doublet splitting in the P-branch has been resolved down to $K = 7$. This may be compared to resolution down to about $K = 22$ in high-dispersion studies using the aluminium arc[2–4]. The averages of all measured doublet components agree with the measurements of Pomeroy[2], so that the only unique part of the present analysis of this band is the determination of the spin-doubling constants from lines of low K-values. Since there has been some disagreement about these constants, we here compare our results with those of Lagerqvist, Nilsson and Barrow[3], and of Sen[4], which are based on lines of high K-values :

	This work	Ref. 3	Ref. 4
γ'	0·019 ± 0·005 cm.⁻¹	0·021 ± 0·005 cm.⁻¹	0·030 cm.⁻¹
γ''	0·008 ± 0·006	0·010 ± 0·005	0·021

Fig. 2 shows a section of the more complex ultra-violet system near 3000 A. for which the hollow-cathode exposure times are about five times those for the green bands and for which only a tentative vibrational analysis has been available[5]. The present work shows that each band consists of two sub-bands, each of which contains two strong branches. Further vibrational and rotational analysis proves that the lower-state constants are those of the $^2\Sigma^+$ ground-state, observed also in the green bands. However, the upper-state $(^2\Pi_i)$ vibrational constants are (in cm.⁻¹) :

$$T_e = 33{,}174{\cdot}6, \quad \omega_e = 728{\cdot}4, \quad \omega_e x_e = 7{\cdot}5$$

rather than the following values taken from ref. 5:

$$\nu_{00} = 33{,}085, \quad \omega_0 = 845, \quad \omega_0 x_0 = 4$$

From rotational analysis of the (4—2), (1—0), (0—0) and (0—1) bands the following constants of the $B^2\Pi$ state have been obtained :

$$B_e = 0{\cdot}6027 \text{ cm.}^{-1}, \; \alpha_e = 0{\cdot}0036 \text{ cm.}^{-1} \text{ and } A_1 = -75{\cdot}78 \text{ cm.}^{-1}.$$

The observed Λ-doubling shows that the Π-state is inverted.

Continuous radiation from the cathode has hindered attempts to record the $B^2\Pi_i - A^2\Sigma^+$ bands expected at 8000 A. Earlier (Innes, K. K., and Innes, R. H. C., unpublished work), by means of a 2·5-kV.amp. arc between aluminium electrodes, these 'red' bands of AlO had been observed between 7900 A. and 8700 A. using exposure times about twenty times those necessary for the green bands from the same source. The red bands were complex and the lines were quite broad, due to the hot, comparatively high-pressure, source. Some of the few, irregularly spaced heads were degraded to the red while others were degraded to the violet. The B-value given above for the B-state is nearly equal to that of the A-state and this accounts, qualitatively, for the observed structure of the red bands, including the distribution of intensity and the paucity of sharp heads. The latter feature is probably responsible for the failure of previous attempts to identify the B—A bands at low dispersion[5,6].

The detailed work on the red bands has been resumed to determine if they can add to the information about the $B\Pi_i$ state which has been obtained from the ultra-violet bands. Detailed analysis of the

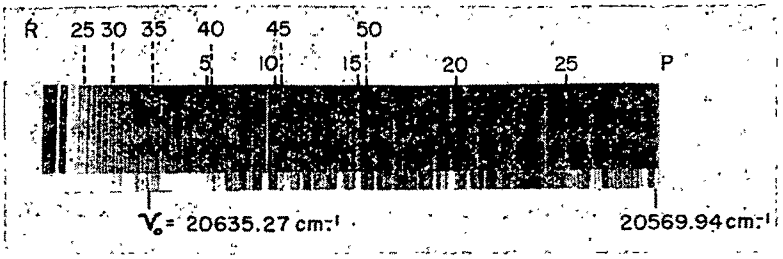

Fig. 1. 0—0 band of the $A^2\Sigma$ -- $X^2\Sigma$ system of AlO (4842 A.)

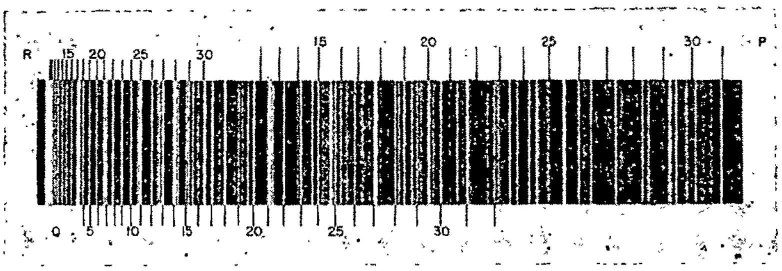

Fig. 2. 0—0 band of the $B^2\Pi_{3/2}$ -- $X^2\Sigma$ system of AlO (3028 A.)

only strong band of the remaining ultra-violet system of AlO is also in progress. A complete report of this work will be published in due course.

Support by the Naval Ordnance Laboratory of White Oak, Maryland, and by the Research Corporation is gratefully acknowledged. We are indebted to Mr. J. U. Upton of White Oak for construction of the discharge tubes used in this work. One of us (K. K. I.) wishes to thank Dr. D. V. Sickman of White Oak for helpful discussions.

Atomic Electron Affinities

ELECTRON affinities of negative atomic ions are now being measured with increased accuracy[1]. The improvement of the experimental results makes a satisfactory theoretical approach to the problem more imperative than ever.

The best available computations of wide applicability are based on the semi-empirical method of extrapolation. This includes the oldest and most commonly employed method of quadratic extrapolation of ionization potentials first suggested by Glockler[2]. This method, *a priori*, should give the electron affinities correct in absolute value; however, many attempts over a period of years failed to produce satisfactory results. The predictions of the quadratic extrapolation are on average 0·5 eV. too low, and when this amount is added to the computed data the results still have an average error of about 0·3 eV. when compared with the best experiments available to-day. This is evident[3] from columns (1) and (2) of Table 1.

It is our feeling that the reason for the failure of the quadratic extrapolation (and related methods) lies in the sensitivity of the method to the underlying extrapolation formula. For this reason it is essential that such a formula be based on physical arguments and justification. A purely mathematical extrapolation of a table of ionization potentials has no chance of success, because the experimental data which are extrapolated here are insufficient in number as well as in accuracy. This experimental situation cannot be expected to improve greatly within the foreseeable future.

We suggest, therefore, a new extrapolation formula which has physical justification and which involves at least two parameters that admit checks by independent methods. We propose that the ionization potential be written in the form:

$$I(Z) = \alpha(Z - \sigma)^2 + \gamma + \frac{a_1}{Z - \sigma} + \frac{a_2}{(Z - \sigma)^2} + R$$

The quantity R is the remainder of the expansion in inverse powers of $(Z - \sigma)$. The corresponding series for $I(Z)$ can be justified as a fairly fast converging perturbation expansion. The five parameters α, σ, γ, a_1, and a_2 are determined from the observed ionization potentials[4] of a given isoelectronic sequence. The resultant function of Z (first four terms of $I(Z)$) is then extrapolated to the respective negative ion. The remainder, R, must be determined by comparison with experiment and is a percentage correction. If the experimental results on I were more accurate, further coefficients a_3, a_4, etc., of the expansion could be determined, and R could then be estimated theoretically. The present experimental accuracy does not permit such a procedure. In the results given, R was chosen to be 10 per cent.

As a check, the parameter α was found to be very slightly larger than $1/n^2$, where n is the principal quantum number, and σ was also found to be in satisfactory agreement with the screening parameters determined in other contexts[5].

It is to be noted that α and σ are determined by extrapolation of the isoelectronic sequence to large Z,

Table 1. ELECTRON AFFINITIES OF NEGATIVE ATOMIC IONS
(All entries in eV.)

Ion	(1) Quadratic extrapolation	(2) Experiment	(3) Proposed extrapolation
B^-	− 0·089	> 0	0·82
C^-	0·83	1·13 ± 0·15	1·21
N^-	− 0·6 ± 1	< 0 ?	0·54
O^-	0·69	1·465 ± 0·005	1·47
F^-	2·93	3·62 ± 0·09	3·62
Al^-	0·50	> 0	1·19
P^-	0·57	> 0	1·33
S^-	2·07	2·07 ± 0·07	2·79
Cl^-	3·05	3·82 ± 0·06	3·84

the first term being an asymptotic value for $Z \rightarrow \infty$. In the quadratic extrapolation the first three terms of the isoelectronic sequence (lowest Z) are used for determining a quadratic in Z. Therefore, this quadratic cannot be justified as an asymptotic hydrogen-like formula. The parameters a_1 and a_2 play an essential part in the numerical value of the electron affinities.

The results are given in column (3) of Table 1 (the observed ionization potentials for the Si^- sequence are insufficient to apply our method) and are seen to agree within experimental error for all observed cases except S^-. The discrepancy in S^- may be due to incorrect experimental data on the ionization potentials of Cl I and its sequence.

A detailed report of this work will be published elsewhere.

Magnetic Viscosity displayed on Hysteresis Loop Traces

[illegible]HE earliest measurements relating the rate of [illegible]ge of flux to applied field under pulsed conditions [illegible] made by Sixtus and Tonks[1]. They measured [illegible]ate of propagation along a nickel wire of a wave-[illegible] of flux change and so obtained a measure of [illegible]agnetic 'viscosity'. More recently, Galt[2] has [illegible]rmed similar measurements involving a single [illegible]in wall in a crystal of nickel–iron ferrite. Since [illegible] I have made measurements of magnetic [illegible]sity in polycrystalline magnesium–manganese [illegible]e ('Ferroxcube' *D*1) during continuous hysteresis [illegible] tracing, this particular ferrite exhibiting a [illegible]ngular hysteresis loop.

[illegible]e method used here involved the superposition of pulsed and a.c. magnetizations. This was accomplished with negative feed-back control of the flux wave-form in the specimen, the apparatus used being fully described elsewhere[3]. It is sufficient to remark that with this apparatus over a wide range of frequency the flux wave-form corresponds almost exactly to the voltage applied to the system.

To produce the required pulse, in addition to the sine wave input normally employed, there was superposed at the same frequency a square wave with the slope of its rising and falling edges adjustable over a wide range. Thus for the duration of each edge the change of flux was rapid and constant, and throughout the remainder of the cycle it was much slower.

At the repetition frequency chosen, 330 c./s., the effect of magnetic viscosity was small, although not negligible. The rate of change in the accelerated portion of flux reversal could correspond to applied frequencies as high as 250 kc./s. or as low as 500 c./s. For these two limits, the increases in magnetizing field required were 96 and 3 per cent, respectively, of the coercive force, measured from the static loop.

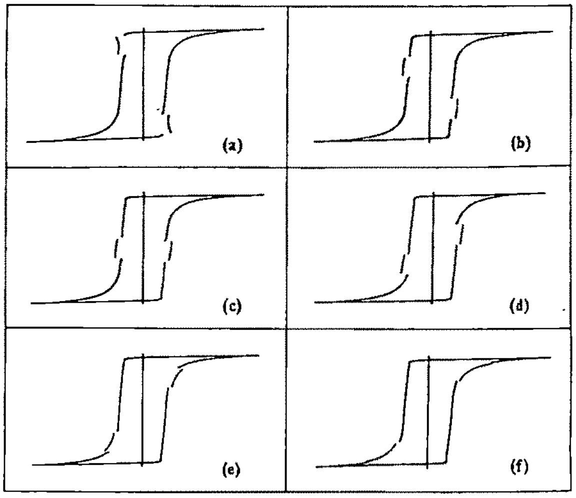

Fig. 1. Hysteresis loops with superimposed a.c. and pulsed excitations

Fig. 1 shows tracings from photographs of hysteresis loops produced by this method. The point of acceleration is shown by an outwards jump in H on the hysteresis loop, and the end of the accelerated portion by a returning jump. For the six different traces the point of acceleration occurs progressively later in the cycle. The accelerated rate of change of B was the same in each, being $1{\cdot}25 \times 10^4$ Wb./m.^{2}/sec. (with $B_m = 0{\cdot}236$ Wb./m.^{2}, $H_m = 500$ amp. turns/m., $H_c = 77$ amp. turns/m.), but it will be seen that the initial step in H progressively decreases from one trace to the next. However, it has been found that the converse is true for the magnitude of the step when measured at the point $B = 0$. In trace (c) this step was 25 amp. turns/m.

The equation $dB/dt = k(H - H_0)$, which is of the same form as those obtained by Sixtus and Tonks and by Galt, was found to apply only when $(H - H_0)$ was large, of the order of 20 amp. turns/m. or more. The constant k was found to vary markedly as the point of acceleration was changed, and to a lesser extent as H_m was varied. The maximum value for k, measured when $B = 0$, was 5×10^3 Wb./m. sec. amp. turns, and its minimum was about 10^3 Wb./m. sec. amp. turns in the linear range; but in the non-linear range when $(H - H_0)$ was small k decreased even further, approaching 10^2 Wb./m. sec. amp. turns.

The departure from linearity at the lower field strengths, which was not experienced by Galt, is apparently due to the polycrystalline nature of the material, which gives rise to a larger number of mobile domain walls. Otherwise, the results for this material, and those obtained by Galt for a single domain wall are of an identical nature.

A Microwave Method of determining the Displacement and Velocity of a Piston in a Hypersonic Gun Tunnel

THE 'hypersonic gun tunnel' is a development of the conventional shock tube, giving a comparatively long running time for aerodynamic testing purposes. Its mode of operation has been fully described[1].

A vessel containing gas at high pressure is initially separated from the main tube or gun barrel at a lower pressure by a metal diaphragm and a light piston. When the diaphragm is ruptured, the piston is driven down the barrel and a strong shock wave forms ahead of it. The shock wave is reflected several times between the end of the barrel and the piston before the latter is finally brought to rest, the slug of air ahead of it being heated and compressed in a non-isentropic manner. This region ahead of the piston can experience very high transient pressures and temperatures.

We particularly wished to study the effect of the mass and shape of the piston on the flow parameters.

The displacement and velocity of a nylon piston in the hypersonic gun tunnel at the University of Southampton has been determined by means of a microwave technique[2]. This method has been devised because it provides a large number of test stations (in this instance 120 over 10 ft.) at which displacement and velocity of the piston can be determined.

The technique regards the steel gun barrel as a resonant microwave cavity and the travelling piston as a tuning plunger moving in the cavity. A radially symmetric wave-guide mode (TM_{01}) is established in the 10-ft. long steel gun barrel of 1·25 in. internal diameter. Microwave power obtained from a reflector klystron operating in the 3-cm. commercial band is launched into the barrel by an axial probe through a wave-guide directional coupler, the latter permitting the simultaneous monitoring of the reflected or transmitted wave system with a single aerial. A crystal diode detects the reflected wave signal from the moving nylon piston. The reflexion-coefficient of the piston is increased by facing it with a shim metal disk. The time between successive standing wave minima indicates the time taken for the piston to move through a half guide wave-length. Displacements and velocities have been measured throughout the period of the piston motion.

The oscillogram (Fig. 1) shows variation of crystal diode voltage with time during a typical run; it was taken 4·0 m.sec. after the diaphragm was ruptured. Analysis indicates that the piston is increasing in velocity from 1,445 ft./sec. to 1,490 ft./sec. over a length of barrel of 3·02 in. during a time-interval of 170 μsec. This requires an acceleration of order 265,000 ft./sec.^{2}. The maximum piston velocity so far observed has been 1,700 ft./sec. If the measured signal is deliberately made asymmetric (by alteration of matching) then it is possible to observe a change of signal phase whenever the piston reverses its direction. This effect has been clearly seen during actual runs.

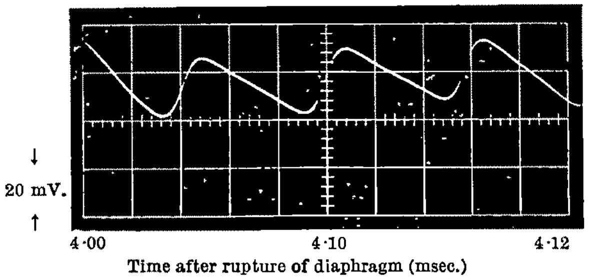

Fig. 1. Variation of crystal diode voltage with time

A raster type of cathode-ray oscillograph display is being developed which will enable the whole run to be recorded, yet have an individual line time-base sufficiently short in duration to enable accurate variations of piston velocity to be determined.

A 'Solid-Image' Microscope

THE disadvantage of the 'solid-image' microscope described by Gregory and Donaldson[1], as they point out, is that objects are seen through a relatively intense haze of background light, rather as if they were immersed in milk. There is a fairly straightforward way around this difficulty, though it entails a loss of some of the elegant simplicity of Gregory and Donaldson's instrument. During 1948–49 I devised and built at King's College a 3-dimensional scanning microscope on the same basic principle[2], which was described briefly in a report on university research in physics in 1949 [3] and exhibited at the College conversazione in that year. The slide carrier w
vibrated in depth between 10 and 20 times a seco
with a saw-tooth motion, by means of a linear elect
magnetic servo. The object, however, was scann
laterally by a flying spot on a cathode-ray tu
and the signal detected by a photomultiplier, exac
as in the 2-dimensional 'flying spot microscope' la
(and apparently independently) described by Rob
and Young[4] of University College, London.
three deflecting voltages and the photomulti
signal were supplied to a 3-dimensional projec
cathode-ray tube display of the type devised for
in radar and electronic computing[5], so that a 's
representation of the object appeared on the sc
and could be rotated at will by calibrated con
which enabled angles to be read directly.

The crucial advantage of the electronic displa
that the signal can be electronically 'inverted' s
to present a negative picture showing object
white on an otherwise dark background. In
way one could readily see single nuclear par
tracks in emulsion (for the study of which the ins
ment was particularly intended) when in a 'positive' picture they were quite obscured by the bright background.

Work on the instrument was unavoidably interrupted in 1949, but my preliminary conclusion was that the astigmatism due to the inevitably poor depth-resolution must limit its usefulness to the study of fairly simple (preferably linear) structures (such as particle tracks, and perhaps nerve fibres). A severe compromise between signal-to-noise ratio, electronic resolving power, and rate of scanning is determined by the brightness of available flying-spot sources, since even ten pictures a second, with only twenty horizontal 'layers' each, require 200 frames to be scanned each second. At such rates, non-uniform scanning[6] was found to be essential to give acceptable resolution in the centre of the picture, and it seemed unlikely that for a tolerable signal-to-noise ratio, resolving power could equal that of conventional instruments. At lower rates, of course, resolution could be as good, or even (with electronic 'sharpening') a little better.

[6] MacKay, D. M., Brit. Pat. No. 592,372 (1947); *Electronic Eng.*, 284 (July 1950).

We were not aware of Dr. MacKay's most interesting experiments in this field when we constructed our first prototype 'solid image' microscope, and it seems unfortunate that his work was interrupted, and not made generally available.

It should perhaps be stressed that our attempt to produce a 'solid image' is based on purely optical principles. A 'flying spot' technique requires scanning in three dimensions, rather than one only, imposing serious demands on the band-widths available with the single channel involved.

It does not seem impossible to produce brightness 'inversion' by optical means. Thus standard dark-ground illumination gives bright objects in a dark field. We are at present experimenting with various types of illumination, in an attempt to produce acceptable contrast and resolution with magnifications sufficient to reveal such structures as nuclear particle tracks in emulsion and suitably stained nerve fibres.

Suppressed Light Emission of the Reaction Zone in Detonation

The detonation of high explosives in water can be photographed with an open camera and a flash light as the explosive gases do not emit light. The method has been used[1] to investigate the spread of shock waves and explosive gases, and to investigate the initiation by shock waves[2]. We have found that it can be used also in certain gases such as butane and propane. The method is not suitable, on the other hand, for explosives with two levels of detonation velocity in the case of low velocity. A great part of the reaction then occurs after the reaction zone has passed and the expanding explosive gases are very luminous even in water.

In detonation with high velocity the original surface of the explosive is luminous due to the emission of light at the passage of the reaction zone. The luminosity of the surface is often very heterogeneous. Compressed TNT thus gives a distinctive pattern of small, rather sharply defined surfaces with different light intensities. Sometimes dark coherent sections appear. In transmitting detonation through water between two coaxial cylindrical charges with plane ends, the receptor charge has at its initiating end a dark band which extends right across the charge, and which increases in its axial length with the transmission distance. The detonation in the receptor charge is slightly delayed in starting, and in the meantime the shock wave from the primary charge is propagated and the dark part of the secondary charge is exposed to a high pressure.

Fig. 1 shows clearly how the light emission of the reaction zone is suppressed by an external pressure of water. The experiment was made with a spherical charge of 50 mm. diameter and two cylindrical charges of 20 mm. diameter and a length of 100 mm. in a cubical tank with a 35-cm. edge-length. The charges were of compressed TNT of density 1·53 gm./cm.^{3}. Behind the tank was placed an argon flash with a pentolite charge and a screen of paper which gave a diffuse light. All charges were initiated with detonation fuses and blasting caps, the spherical charge in the centre and the cylindrical charges at their lower end. The detonation fuses were connected to a common fuse, and their lengths were adjusted so that the argon flash was lit when the shock wave from the spherical charge met the detonation front approximately at the middle of the right cylindrical charge. It is evident from Fig. 1 that the light emission diminishes very rapidly when the reaction zone enters the pressure field of the shock wave from the spherical charge. The pressure was about 2,500 atmospheres. The left cylinder charge was initiated later, and its boundary line is therefore somewhat lower down.

To determine whether the dark part of the charges detonates in a normal manner, an experiment was made with a charge of two cylinders joined at right angles (Fig. 2). It was initiated at the lower end of the right leg so that the detonation-front met the shock wave from the spherical charge below the angle joint. The charge is dark above the intersecting line, but the detonation proceeded round the corner and on its downward course along the left leg it passed the shock wave. Below the passage line the charge again becomes luminous. In this experiment the flash was lit when the detonation front was in the dark part of the charge. The outgoing shock wave gives further confirmation that the dark part of the charge detonated in a normal manner.

Measurement of the porosity of the TNT charges has given values between 5 and 8 per cent by volume. It seems reasonable to assume that the pores of the surface layer become filled with water when the shock wave passes, and that as a consequence the luminosity weakens. It was found, however, that evacuated and water-filled charges gave a similar pattern to that of charges with air-filled pores, although the luminosity was weaker. Further, the suppression of light was about the same in cast as in compressed TNT. Part of the black-out may therefore be directly due to the pressure.

For cast pentolite with 60 per cent PETN and 40 per cent TNT the emission of light is also

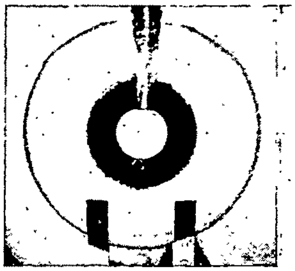

Fig. 1

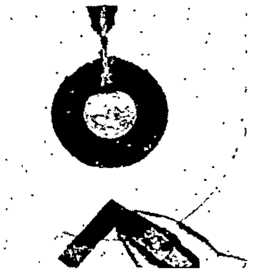

Fig. 2

diminished by a shock wave in water, but the effect is less than for TNT. Compressed PETN shows no decrease in the luminous intensity.

We wish to thank Mr. T. Edlund, manager of the Nitroglycerine Company, for permission to publish this work.

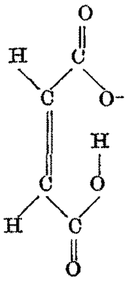
CHEMISTRY

Intramolecular Hydrogen Bonding in Heterocyclic Systems

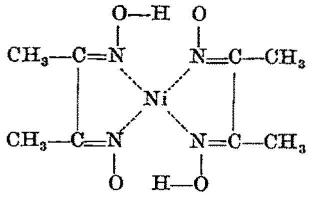
The hydrogen bond is usually described as unsymmetrical, with the hydrogen atom nearer one of the two bonding atoms, and the energy of bonding is considered as due to electrostatic and delocalization energy. The principal valency bond structures considered are I, II and III, and it has been shown[1] that when the O—O distance is 2·5 A. these three structures have the relative weights 60·3, 28·4 and 11·3. Resonance of a purely covalent character is not considered to play a part as this would require the hydrogen atom to be symmetrically placed between the two bonded atoms, and Donohue[2], by extrapolating Pauling's bond-order/bond-length relationship, has calculated that for such a bond the O—O distance could not exceed 2·4 A. However, most of the detailed studies of this problem have been concerned with intermolecular hydrogen bonds, and it is suggested here that in the cyclic systems involved in intramolecular hydrogen bonds, covalent forces play a much larger part.

$$\underset{\text{(I)}}{\text{—O—H}\cdots\text{O}} \qquad \underset{\text{(II)}}{\text{—}\overset{-}{\text{O}}\ \overset{+}{\text{H}}\cdots\text{O}} \qquad \underset{\text{(III)}}{\text{—}\overset{-}{\text{O}}\quad \text{H—}\overset{+}{\text{O}}}$$

It has been pointed out[3,4] that if covalent forces played an appreciable part in hydrogen bonding, considerable alterations in the O—H stretching band in the infra-red would be expected. In the case of intermolecular hydrogen bonds the shifts in the O—H band from 3,200 cm.$^{-1}$ are usually small, and the intensity of the band is increased; but in several cases of intramolecular hydrogen bonding, the O—H band has been very drastically shifted and its intensity greatly diminished. Cardwell, Dunitz and Orgel[5] noted that the O—O distance in the hydrogen maleate ion IV should be very short (less than 2·45 A.), and that the infra-red spectrum revealed no detectable absorption from 5,000 cm.$^{-1}$ to 1,575 cm.$^{-1}$. The *bis*-dimethylglyoximinate nickel[6] or cobalt[7] complex V has an O—O distance of 2·44 A. and its O—H stretching band greatly weakened and displaced to 1,900 cm.$^{-1}$.



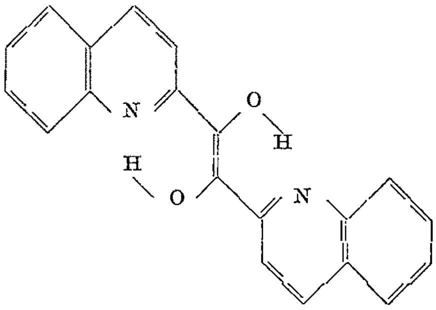
(IV)



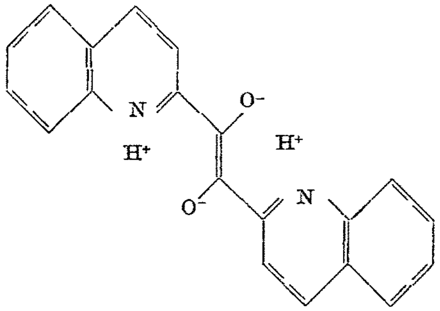
(V)

The effect of covalent resonating forms would be expected to be greater in compounds where the hydrogen bonded system could become part of an extended resonating system, and we have, therefore, examined the infra-red spectra of some heterocyclic intramolecular hydrogen bonded compounds, for example, 1,2-di-2′-quinolylethene-1,2-diol (quinaldoin), VI, deoxyquinaldoin, VII, and 1,2-di-3′-*iso*quinolylethene-1,2-diol, VIII. In these compounds the OH, NH and C=O vibrations are so modified that none of the compounds shows any absorption between 5,000 cm.$^{-1}$ and 1,625 cm.$^{-1}$.

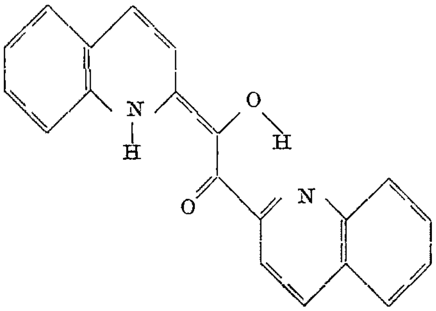
It is suggested that the lack of any absorption before 1,600 cm.$^{-1}$ in the compounds studied is due to intramolecular hydrogen bonding, stabilized by considerable resonance contributions from covalent forms (VI*a*, *c*) and facilitated by the cyclic nature of the system, that is, an essentially non-polar hydrogen bond. It has been shown[8] that the equilibrium O—H distance increases exponentially as a second electronegative atom approaches. Calculations assuming normal bond-lengths and bond-angles of 120° show that the O—N distance in these molecules lies be-



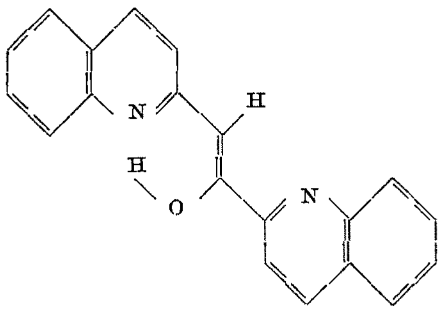
(VI*a*)



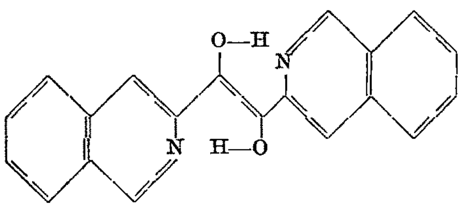
(VI*b*)



(VI*c*)



(VII)



(VIII)

tween 2·41 and 2·45 A., depending on the degree of double-bond character assumed. Taking the O—N distance to be 2·45 A. and the equilibrium O—H distance to be 1·15 A., Coulson and Danielsson's[1] method of calculation gives the relative weights of VI*a*, *b* and *c* as 52·2, 20·1 and 27·7, respectively. The covalent form VI*c* therefore makes a very real contribution. Due to the cyclic form of the hydrogen-bonded system electron delocalization does not involve charge transfer, and therefore the intensity of the O—H band is diminished, in contrast to the increase in intensity observed in intermolecular hydrogen bonds, where charge transfer does occur (III). This explanation could also be applied to the anomalous infra-red spectra of 2-phenacylpyridine derivatives[9], β-keto enols and β-iminoketones[10].

We therefore suggest that where resonance is possible in intramolecular hydrogen bonds in heterocyclic systems, covalent forces play a considerable part and that such systems[11] would repay further study, particularly with reference to the interatomic distances involved.

Infra-red spectra were measured in bromophthalene and perfluorkerosene pastes so there would be no possibility of a weak band being masked by the CH absorption of paraffin at 2,900 cm.$^{-1}$.

We wish to thank Dr. D. Ll. Hammick for his kind encouragement, and Mr. R. Wolley for his assistance with some of the experimental work.

Heterogeneous Atomization of Hydrogen and Oxygen

BECAUSE of its chemical simplicity, the process of atomization of hydrogen at a surface is free from many of the ill-defined parameters which are important in more complicated heterogeneous reactions and which make their interpretation equivocal. The reaction over tungsten was discovered by Langmuir[1] and investigated quantitatively by Bryce[2] and Ivanoiskaya and Mochan[3]. The experimental arrangement employed by these authors consisted of a tungsten filament suspended in hydrogen, the wall of the reaction vessel being coated with a hydrogen-atom trapping agent so that the reaction velocity could be determined by the measurement of the rate of fall in the pressure of hydrogen. Bryce used molybdenum oxide as the hydrogen-atom trap, while Ivanoiskaya and Mochan used potassium. They found that the rate of atomization was accurately proportional to $\sqrt{P}$ in the pressure range 10^{-2}–10^{-3} mm. of mercury and the energy of activation (E) was 45 kcal./mol. or rather less.

Two atomization mechanisms are possible :

$$W - \mathrm{H} \rightarrow W + \mathrm{H} \tag{1}$$

$$\mathrm{H}_2 + W \rightarrow W - \mathrm{H} + \mathrm{H} \tag{2}$$

where W denotes the tungsten surface and $W - \mathrm{H}$ an atom of hydrogen adsorbed thereon. The assumption is made that the equilibrium $\mathrm{H}_2 + 2W \rightleftharpoons 2W - \mathrm{H}$ is effectively maintained throughout the reaction. Roberts and Bryce[4] applied the principle of detailed balancing to the two possibilities and showed that mechanism 1 yielded $\sqrt{P}$ kinetics only for $\theta \ll 1$, while mechanism 2 required $\theta \sim 1$ for this result, but in each case $E = \frac{1}{2}D(\mathrm{H}_2)$. Immobility of the adsorbed layer is implicit in their discussion. Miller[5] and Laidler and his co-workers[6] have discussed the reaction from the statistical point of view. Mechanism 2 has been consistently and, as we now believe, incorrectly favoured in these treatments.

The fact that neither mechanism 1 nor 2 was capable of adequately describing the experimental results encouraged us to repeat the investigation of the kinetics of the reaction. Molybdenum oxide was employed under carefully controlled conditions as the hydrogen-atom trap, and the vacuum technique was such as to ensure clean surfaces. The $\sqrt{P}$ rate law was found to be obeyed over the pressure-range 10^{-2}–10^{-6} mm. at about 1,200° K. and the fully corrected value of E was $52 \cdot 6 \pm 1 \cdot 0$ kcal./mol. at about 1,200° K., these observations being combined in the equation :

$$\text{rate of atomization} = 18 \times 10^{24}\,(P_{\mathrm{H}_2}\ \text{mm.})^{1/2}\ \exp(-52600/RT)\ \text{atoms cm.}^{-2}\ \text{sec.}^{-1}$$

These findings are compatible only with mechanism 1. An analysis of the atomization and recombination processes indicates that the adsorbed layer of hydrogen has complete two-dimensional freedom on the surface at these temperatures and further, that the ratio of atomic to molecular hydrogen desorbed from the surface has the value predicted by the equilibrium constant (K) for the reaction $\mathrm{H}_2 \rightleftharpoons 2\mathrm{H}$, the temperature and molecular pressure being that of the filament and the ambient gas respectively (cf. Doty[7]).

These new results have two important consequences. First, the reaction is expected to become first order with respect to the molecular hydrogen pressure at a sufficiently low value of P_{H_2}/K, and this change in rate law has been observed in the expected region, namely, 10^{-6} mm. at 1,800° K. Secondly, the rate is independent of coverage; it is thus independent of surface structure and is determined solely by the area exposed to molecular hydrogen. A study of the atomization of hydrogen over platinum and gold supports this view.

We have also studied the atomization of oxygen over platinum using a reduced form of molybdenum oxide as the oxygen-atom trap. Again, $\sqrt{P}$ kinetics are found over an extended pressure-range and the activation energy is accurately $\frac{1}{2}D(O_2)$. Thus the present investigation, the details of which will be published later, support mechanism 1 as the process by which both hydrogen and oxygen are atomized heterogeneously.

We are grateful to Dr. B. M. W. Trapnell for initiating this investigation and to the Billingham Division of the Imperial Chemical Industries, Ltd., for financial support. We also wish to thank Dr. T. B. Grimley for much valuable discussion.

Analysis of Light Hydrocarbon Gas Mixtures

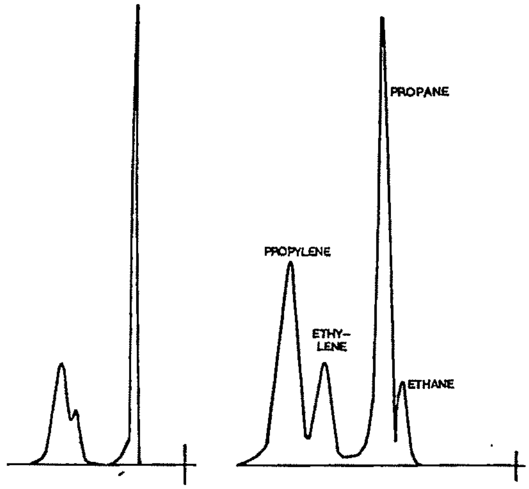
IT is a common analytical requirement to separate mixtures containing ethane, ethylene, propane and propylene, and, while gas chromatographic methods have been designed to separate the C_2 and C_3 gases and also the olefines from the saturated compounds, there is not, in our experience, any simple method reported for the resolution of all four gases on one column.

Olefines are cleanly separated from the saturated hydrocarbons on a column packing consisting of a saturated solution of silver nitrate in ethylene glycol supported on graded 'Celite'[1]. The C_2 gases are separated from the C_3 by a tri-*iso*butylene/'Celite' column[2]. Attempts to achieve separations by use of these two columns in series were unsuccessful (Fig. 1*a*), as were similar attempts by Bednas and Russell[2].

The technique of using a physical mixture of these two packings in one column was therefore tried. The two packings, prepared separately as before, were mixed together mechanically; this did not appear to impair their efficiency or useful life in any way. On a W-shaped column, 4 m. long × 6 mm. internal diameter, separation of all four gases was readily accomplished at room temperature and Fig. 1*b* shows a typical chromatogram obtained with this mixed packing.

The same mixture was used for each run.

Column dimensions: 4 m. × 6 mm. internal diameter; carrier gas: 0·4 l./hr. nitrogen; inlet pressure: 758 mm.; outlet pressure: 712 mm.; column and katharometer temperature: 25° C. So far as we are aware this is the first occasion on which the use of such a physically mixed packing has been reported.



(*a*) (*b*)

Fig. 1. *a*, Series columns; *b*, mixed packing

Further work has shown that it is also quite possible to separate *iso*butene from the four gases previously mentioned on the same column.

Kinetic Isotope Effect in the Bromination of Dimethylaniline

THE recent account by Shilov and Weinstein[1] of a kinetic isotope effect in the iodination of some aromatic amines prompts us to report the observation of a similar effect in the bromination of dimethylaniline.

The absence of a hydrogen isotope effect in the iodine-catalysed reaction between molecular bromine and benzene[2] shows that the C—H bond at the position of substitution is not appreciably stretched in the transition state, though the bond may have changed its hybrid character from sp^2 to sp^3, forming the Wheland intermediate[3] (I, X = Br). Other studies[4] have indicated that, in general, the degree to which the Wheland intermediate is formed in the

Naphthalene	7·3
Phenanthrene	7·4

transition state for aromatic substitution is only partial (for example, II). If the degree of formation of the intermediate in the transition state were constant in a series of aromatic hydrocarbons for a given reagent, the frequency factor of the reaction should increase with the size of the hydrocarbon, as the positive charge would be more dispersed in the transition states of the larger aromatic molecules, and the entropy of activation due to solvation would be correspondingly smaller. However, the contrary trend has been observed[5] (Table 1), suggesting that the more reactive the aromatic hydrocarbon, the more completely formed is the Wheland intermediate in the transition state for aromatic halogenation.

With a very reactive aromatic compound it appeared possible that the passage from the Wheland intermediate to the products, that is, C—H bond-breaking, might become the rate-determining step of a halogenation reaction (for example, III), so that a kinetic hydrogen isotope effect would be observed. Prior to the work of Shilov and Weinstein[1], all kinetic isotope effects found in aromatic substitution reactions could be ascribed[6] to rate-determining C—H bond-breaking in relatively stable neutral or zwitterionic intermediates (for example, IV). To obviate such a possibility in the present study, dimethylaniline was selected as the reactive aromatic compound, and molecular bromine was chosen as the substituting reagent, since the absence of a kinetic isotope effect with this reagent had been demonstrated in the case of benzene[2]. 2,4,6-Trideuterodimethylaniline was prepared by five successive exchanges of dimethylaniline sulphate with deuterium oxide at 100° C., the extent of the exchange, as measured by infra-red spectroscopy, being more than 90 per cent. The rates of reaction of dimethylaniline and its 2,4,6-trideutero-derivative (0·005 and 0·0075 *M*) with bromine (0·003 *M*) were measured at 25 ± 0·01° C. in aqueous sulphuric acid (6·4 *M*) containing an excess of bromide ions (0·025 *M*) by Bell and Ramsden's method[7]. At both amine concentrations a kinetic isotope effect (k_H/k_D) of 1·8 was observed. With the absence of such an effect in the bromination of benzene[2], the present result suggests, like the trend of the frequency factors for the reaction of chlorine with the aromatic hydrocarbons (Table 1), that the nature of the transition state in aromatic substitution varies not only with the substituting reagent[4] but also with the aromatic molecule attacked, showing less resemblance to the reactants in the case of the more reactive aromatic compounds.

Exchange Reaction induced by Radiation between Diethyl Sulphate and Labelled Sulphuric Acid : a Possibly Ionic Reaction

ALTHOUGH ionization reactions represent one of the most important processes in the interaction of radiation with matter, relatively little interest has been shown in reactions involving ionic species with the exception of the ion-molecule reactions recently much discussed[1]. Since ionization is one of the most important processes in the interaction of radiation with matter, it is felt that a study of reactions possibly involving ionic intermediates may provide a most interesting and perhaps fruitful area of radiation research. One such system appears to be the exchange reaction induced by radiation between diethyl sulphate and radioactive sulphate ion, where any appreciable formation of diethyl sulphate-^{35}S may conceivably require $C_2H_5^+$ as an intermediate.

In our experiments, commercial diethyl sulphate was purified by vacuum distillation. Aliquots of sulphuric acid labelled with sulphur-35 (0·2–0·5 mc.) and unlabelled sulphuric acid carrier were evaporated in glass irradiation-cells and 2 ml. of the purified diethyl sulphate was added, after which the cells were evacuated and sealed off. The samples were irradiated with a cobalt-60 source (~1·5 × 10^5 r./hr.), returned to the vacuum line for pressure measurements, and finally the organic phase was purified to check for any exchange reactions.

The irradiated samples were treated in the following manner. Unincorporated sulphuric acid-^{35}S and any ethyl hydrogen sulphate-^{35}S formed were extracted from the organic phase by means of carriers in the form of aqueous sulphuric acid. The extraction was continued until the sulphur-35 activity in the extractant became negligible. After the extractions, the diethyl sulphate was further purified by double distillation on the manifold and hydrolysed to the inorganic sulphate by vigorous refluxing with alcoholic sodium hydroxide. The $^{35}SO_4^{=}$ so obtained was precipitated with barium chloride and counted as infinitely thick samples using an end-window Geiger–Müller tube and a scaler in the standard manner[2].

Table 1. RADIATION-INDUCED EXCHANGE BETWEEN $(C_2H_5)_2SO_4$ AND $H_2{}^{35}SO_4$

The samples used consisted of 2·5 × 10^{-6} mole of sulphuric acid (containing 200–400 µc. of sulphur-35) in 1·54 × 10^{-2} moles of diethyl sulphate (2 ml.). All samples were allowed to stand for the same length of time before processing

Irradiation dose (rads)	10^{3}*	8 × 10^{6}	2·56 × 10^{7}
Average percentage of sulphur-35 activity incorporated	0·9	3·5	6·9

* Due to the sulphur-35 beta activity

For control purposes, unirradiated samples were also processed and counted in an identical manner. The results (Table 1) show that the cobalt-60 irradiated samples undergo a considerably greater exchange than the samples which were not irradiated with the cobalt-60 source. The enhanced extent of exchange by irradiation suggests the possible presence of either (*a*) reactions involving ionized molecules of diethyl sulphate and their dissociation products, for example, the $C_2H_5^+$ ion, or (*b*) reactions involving the $C_2H_5\cdot$ radical and the $^{35}SO_4$: biradical. If ionic species were involved, the probable reactions would be :

$$(C_2H_5)_2SO_4 \rightsquigarrow (C_2H_5)_2SO_4^{+} + e^{-}$$

$$(C_2H_5)_2SO_4 + e^{-} \rightarrow (C_2H_5)_2SO_4^{-}$$

$$(C_2H_5)_2SO_4^{+} + {}^{35}SO_4^{=} \rightarrow C_2H_5SO_4 + C_2H_5{}^{35}SO_4^{-}$$

$$C_2H_5SO_4 \longrightarrow \text{dissociation products}$$

$$C_2H_5{}^{35}SO_4^{-} + (C_2H_5)_2SO_4^{+} \longrightarrow (C_2H_5)_2{}^{35}SO_4 + C_2H_5SO_4$$

$$C_2H_5^{+} + {}^{35}SO_4^{=} \rightarrow C_2H_5{}^{35}SO_4^{-} \xrightarrow{+C_2H_5^{+}} (C_2H_5)_2{}^{35}SO_4$$

In spite of the rather low concentration of the ionic species involved (about 10^{17} sulphuric acid molecules or ions versus about 10^{22} diethyl sulphate molecules per ml.) the exchange reaction appears to be a relatively efficient process. Possible applications of these reactions may be (*a*) tagging of various sulphur compounds as well as substances which cannot be conveniently tagged by other techniques and (*b*) studying of the behaviour of ionic species produced by radiation in a liquid system.

Peak Dimensions in Gas Chromatography

WHATMOUGH'S observations[1] can be explained if the absorption isotherms of his packing material are non-linear and if one takes account of variations of flow velocity in the column[2].

At a point where the vapour concentration is c let the total quantity of vapour, including that absorbed, be q per unit volume of free space. If the flow velocity is u, then:

$$\frac{dq}{dt} - \frac{dc}{dt} = -\frac{du}{dx} \tag{1}$$

If local equilibrium is attained instantaneously and longitudinal diffusion is negligible, then:

$$\frac{d(uc)}{dc}\left(1 - \frac{dc}{dq}\right) = \frac{du}{dc} \tag{2}$$

If u_0 is the velocity in regions containing pure carrier gas, then since q is a function of c, it is clear from (2) that u/u_0 is also a function of c. Take the case of a packing in which:

$$q = c + \frac{\sigma c}{1 + \alpha c} \tag{3}$$

If the column is being saturated by passing in a mixture of concentration c, then the quantity of gas entering per unit volume saturated is:

$$1 + \frac{\sigma}{1 + \alpha c} \tag{4}$$

and the quantity of carrier gas leaving the exit is:

$$1 + \frac{\sigma(1 - c)}{(1 + \alpha c)} \tag{5}$$

This gives:

$$\frac{u}{u_0} = \frac{1 + \sigma + \alpha c}{1 + \sigma + \alpha c - \sigma c} \tag{6}$$

The rate of advance of the front is:

$$u_0(1 + \alpha c)/(1 + \sigma + \alpha c - \sigma c) \tag{7}$$

At small concentrations the rate of advance is $u_0/(1 + \sigma)$; let $X = u_0t/(1 + \sigma)$ and let time be measured from the instant that the injection of a sample is complete. If q is assumed to be a function of x/X in the regions where it is neither zero nor constant, then:

$$\frac{\partial q}{\partial X} = -\frac{x}{X}\cdot\frac{\partial q}{\partial x} = -\frac{1 + \sigma}{u_0}\cdot\frac{\partial(uc)}{\partial x}$$

$$\text{whence } \frac{x}{X} = (1 + \sigma)\frac{d}{dc}\left(\frac{u}{u_0}c\right)\Big/\frac{dq}{dc} \tag{8}$$

c is zero when $x < X$ and beyond this point increases nearly linearly at a rate inversely proportional to X. This continues until $c = c_0$, the sample concentration, or until the front is reached at some lower concentration c_m. The front remains sharp. If L is the length of the column, then the total quantity of vapour leaving the exit per unit free cross-section is given by:

$$Q = \int uc\,dt = (1 + \sigma)\int_0^{c_m}\frac{u}{u_0}\,c\cdot\frac{d(L - X)}{dc}\,dc \tag{9}$$

From (3) $\frac{dq}{dc} = 1 + \frac{\sigma}{(1 + \alpha c)^2}$ and from (6) and (8) it is possible to evaluate (9).

If L is long enough to make c_m less than c_0 then:

$$\frac{1}{c_m} - \frac{\sigma\alpha c_m}{2(1 + \sigma)^2} + \ldots = \left\{\frac{L\sigma(1 + \alpha)}{Q}\right\}^{1/2} - \alpha \tag{10}$$

In practical cases the term in c_m will be negligible.

The quantity of vapour deduced from the area of a recorder peak is given by:

$$Q' = u_0\int c\,dt \tag{11}$$

To a sufficient approximation:

$$Q' = Q\left(1 - \frac{2}{3}\cdot\frac{\sigma}{1 + \sigma}c_m\right) \tag{12}$$

Taking the ratio of peak area to peak height as a measure of peak width:

$$\frac{Q'}{c_m} = \left\{QL\sigma(1 + \alpha)\right\}^{1/2} - Q\left(\alpha + \frac{2}{3}\cdot\frac{\sigma}{1 + \sigma}\right) \tag{13}$$

This is a maximum when:

$$\left\{\frac{L\sigma(1 + \alpha)}{Q}\right\}^{1/2} = 2\alpha + \frac{4}{3}\cdot\frac{\sigma}{1 + \sigma} \tag{14}$$

The value of dc_m/dQ is a minimum when:

$$\left\{\frac{L\sigma(1 + \alpha)}{Q}\right\}^{1/2} = 3\alpha \tag{15}$$

Whatmough uses an arbitrary concentration scale so that quantitative comparisons are impossible, but for values of c_0 exceeding 0·2 his peak maxima are well represented by:

$$\frac{K}{c_m} = \left(\frac{15}{c_0}\right)^{1/2} - 1 \tag{16}$$

Diffusion has little influence on peak width if Q is large; but if it is small, diffusion predominates and gives an almost Gaussian distribution with a maximum proportional to Q; this accounts for the linear start of his peak height curve.

From (16) the minimum value of dc_m/dc_0 should occur when $c_0 = 5/3$ and the maximum peak width at a not very different value; this accounts for the straightening of the peak height curve and the slow change of width at high values of c_0.

GEOLOGY and MINERALOGY

Structural Control of Polymorphism in Micas

The extensive polymorphism shown to exist among the mica minerals by Hendricks and Jefferson[1] has been confirmed by a number of workers in more recent years[2,3]. Polymorphism similarly has been clearly demonstrated for other layer lattice silicates, for example, for the chlorites by Brindley, Oughton and Robinson[4].

It is well known that micaceous minerals can form polymorphs principally because the surfaces of the individual silicate layers are composed of oxygen atoms arranged in hexagonal networks. Thus the successive layers can be superimposed or stacked in a number of different ways, in each of which the two hexagonal layer surfaces pack together identically, oxygen to oxygen; but these different ways of layer stacking can give rise to different symmetries and unit cells in the total structure. The successive layers may be regarded as being related to each other by regular rotations between layers, this being geometrically equivalent to regular translations of successive layers along either the a-axis or the b-axis or both. (The concept of rotations between layers is geometrically simpler, but that of translations may be more acceptable physically.)

Smith and Yoder[5] have developed a theory based on these ideas to predict all the possible polymorphs of micas which may occur. They have shown that there are six simple ways of stacking mica layers in an ordered manner, these being based on "inter-layer stacking angles" as follows: $1M$ (one-layer monoclinic) on 0° stacking angles, $2M_1$ on alternating 120° and 240° angles, $3T$ (three-layer trigonal) on 120°, $2O$ (two-layer orthorhombic) on 180°, $2M_2$ on alternating 60° and 300°, and $6H$ (six-layer hexagonal) on 60° angles. While Smith and Yoder discussed the possible factors governing the growth of various polymorphs (including forces due to distortions of the hexagonal oxygen networks) it was not possible to explain, on the evidence then available, their observed relative abundance. It was noted, however, that only the $1M$, $2M_1$, and $3T$ polymorphs are common in Nature, and that $2O$ and $6H$ specimens had not been found at all. Lepidolite specimens crystallizing with the $2M_2$ structure have been described by Levinson[2] and others.

The rarity or non-occurrence of the $2O$, $2M_2$ and $6H$ mica polymorphs appears to me to be explained fairly satisfactorily by the observed departures of layer-lattice silicates from their ideal structures, as reported in several recent analyses (of vermiculite[6], of dickite[7] and of amesite[8]). In each of these the oxygen network is distorted from a hexagonal array to one in which the oxygen atoms are arranged on two interpenetrating triangles of different sizes. For vermiculite these are two isosceles triangles with the equal sides 4·35 and 4·84 A. respectively; but it is to be noted that both triangles are very nearly equilateral. Mathieson and Walker point out that the distortion can be viewed as due to a rotation of triads of oxygen of about 5½°. I am at present re-investigating the $2M_1$ muscovite structure; and while the atomic parameters are not finally fixed it is clear that a similar—though probably greater—distortion of the oxygen network exists in this mica.

The net effect of such distortions is to lower the symmetry of the surface layer from hexagonal to approximately, though not precisely, trigonal. Those polymorphs which result from interlayer stacking angles of 0°, 120° or 240° may therefore occur fairly readily, though their relative abundance may depend on how nearly trigonal the oxygen network is in a given mineral. But those polymorphs based on angles of 60°, 180° or 300° may be expected to occur infrequently (and only as fine-grained specimens), since considerable adjustments of oxygen positions on each layer face would be necessary.

The above argument seems to be supported by the fact that the $2M_2$ mica structure has only been observed for lepidolites. Smith and Yoder[5] pointed out the controlling effect of the linked array of SiO_4 and AlO_4 tetrahedra on the dimensions of the micas; and Newnham and Brindley[7] have attributed the rotations of these tetrahedra in dickite to the misfit of the 'oversize' tetrahedral layer on to the smaller octahedral layer. The lepidolites have less tetrahedral aluminium-for-silicon substitution than other micas, and this layer will thus have dimensions more nearly equal to the (smaller) octahedral layer.

It may be expected that there will therefore be less strain in lepidolites due to tetrahedral–octahedral misfit. This suggests that the oxygen configuration will show a smaller degree of distortion from the ideal hexagonal symmetry, thus allowing a polymorph based on 60° rotations (such as $2M_2$) to occur.

This hypothesis can, of course, only be tested satisfactorily by an accurate analysis of the $2M_2$ lepidolite structure.

For micas other than lepidolites and brittle micas the tetrahedral layer has cation composition $Si_{3/4}Al_{1/4}$, and this network, according to Smith and Yoder[5], should have b-dimensions of $9 \cdot 30 \pm 0 \cdot 06$ A. There will be little distortion of the oxygen hexagons in those micas having a b-axis close to this value (for example, phlogopites and some biotites). If the above argument is valid then the $2O$, $2M_2$ and $6H$ polymorphs may occur among these micas.

Some Palæomagnetic Investigations on Chinese Rocks

Previous palæomagnetic investigations[1] on European and North American rocks agree in suggesting that those areas were in such a position that the pole appeared to lie on or near the Chinese mainland from Upper Palæozoic to Mesozoic times. If the geology of China is examined for those same periods, the climate indicated is more equatorial than polar[2]. These two apparently contradictory facts make the palæomagnetic study of Chinese rocks particularly interesting, and account for the publication of the results of the first collection from China despite the small number of samples.

The collection was comprised of some eleven samples, of which eight were of the Tertiary Kansu Series collected at three sites in Kansu, while the remaining three were of red Middle Silurian siltstones from the southern part of Yumen, Kansu province. The Tertiary rocks unfortunately were magnetically unstable, being characterized by low intensities of magnetization and scattered results. The measurements on the Silurian rocks yielded a more consistent pattern (Fig. 1). The mean declination was N. 66·4° W., mean inclination + 55·3°, with a circle of confidence of 8·5° calculated from 17 measured disks. The mean intensity of magnetization was $8 \cdot 8 \pm 3 \cdot 8 \times 10^{-6}$ e.m.u./cm.[3].

The position of the ancient pole was 168° W. 49° S. or 12° E. 49° N., which compares with the Silurian pole from North America of 138° E. 19° N. and by extrapolation an estimated position of a European pole in 165° E. 22° N. If this Chinese result is confirmed by further collections, the following implication, first suggested by Nairn[3] as a result of comparing Permian palæoclimatic and palæomagnetic data, would seem to be valid, namely, that differential movement occurred between Europe and North America and Eastern Asia. This is a significant addition to the Continental Drift theory, for it implies that at the time when Gondwanaland was a single unit, China at least was not part of the Laurasian continent. Further investigation of this possibility is at present in progress.

Chemical Composition of Tektites

In a recent communication[1], Prof. H. Urey makes the following statement: "Tektites have chemical compositions remarkably similar to those of the more acid sedimentary rocks. This is true for the major and minor constituents. (I have been privileged to see analyses as yet unpublished on these minor constituents.) Such a chemical composition is not produced by any other naturally occurring chemical processes that we know of, except perhaps in very rare and special circumstances". Similar statements have appeared in other papers dealing with tektites, and give the impression that their compositions can be explained only by the fusion of sedimentary rocks.

One may reasonably ask which are these "more acid sedimentary rocks" to which Prof. Urey refers. I do not know any publication in which analyses of tektites are directly compared with those of sedimentary rocks. The most comprehensive compilation of tektite analyses is that of Barnes[2]. In discussing these analyses Barnes applies certain criteria for suspecting a sedimentary origin from the chemical composition (excess of aluminium oxide, potassium oxide > sodium oxide combined with magnesium oxide > calcium oxide and very great excess of silicon dioxide). On the basis of these criteria he concluded that: "There is a strong suggestion that Darwin glass, bediasites, and possibly the moldavites and Ivory Coast tektites are fused sediments. The indochinites, billitonites, and australites on this basis are most closely allied to the igneous rocks".

Nevertheless, a rapid survey of published analyses shows the existence of igneous rocks of comparable composition to each of the principal tektite types (Table 1). The igneous rock analyses were selected from Washington's compilation[3], the tektite analyses from Barnes's monograph[2]. An analysis of each tektite type is paired with the analysis of an igneous rock; the correlation within each pair is on the whole very close.

It is incumbent on those claiming near identity of composition between tektites and sedimentary rocks to show that an equally close correlation is possible between these tektite analyses and analyses of individual sedimentary rocks. Even if such a correlation can be established, it should be clear from Table 1 that material with the chemical composition of tektites can be produced by more than one naturally occurring chemical process. To argue that the chemical composition of tektites indicates that they

Glaciation in the Jammu Hills

MUCH evidence of the last or Pleistocene Ice Age has been observed in various parts of the Central and the Lesser Himalayas. Lieut.-Col. J. L. Grinlinton has referred to the shape of polished and striated or grooved rock surfaces in the Liddar and Sind Valleys of the Kashmir Himalayas[1]. Many terminal moraines have also been noticed on the southern flank of the Pirpanjal at altitudes of somewhat less than 8,900 ft.; but no traces of the Pleistocene glaciation have been so far discovered anywhere in the Jammu Hills south of the Pirpanjal.

My colleague, Mr. T. R. Bhatia, and I recently visited Tringla, close to Batote hill station 78 miles from Jammu. Batote is situated at lat. 33·7° and long. 75·20° at an altitude about 5,000 ft. above sea-level. This hill station and the entire country from Udhampur to Peera and leading to Srinagar, Murree and beyond in West Pakistan, to Teetwal in the north-west and for a considerable distance eastwards is covered by the rocks belonging to the Murree series, of Oligocene and Lower Miocene age.

Our attention was attracted in this series by a few outcrops of the compact and hard sandstone which showed an unusual degree of smoothness. A closer examination of these outcrops revealed a number of grooves, roughly parallel to one another, running in a north–south direction and 5–9 in. long. Evidently these were glacial striæ on the polished sandstone dipping roughly southwards at an angle of about 40°, furnishing convincing proofs of their having been produced by glacial action during the Pleistocene Ice Age. The grooves possessed a virtually original freshness and appeared to have been rubbed off from the neighbouring polished surface. In one sandstone projection a fairly large cut with polished sides was seen. This must have been carved by the silt-charged water when the ice was in the process of melting. Further investigation near the same spot showed a number of large boulders with polished and grooved surfaces. On one of them the grooves were intact, but the polish had completely gone. Similar observations were made about 1 mile to the east towards the Chakou Nala.

In our opinion, the Patni Top area south of Batote, altitude 7,000 ft., served as the gathering ground for the snow and ice during the Pleistocene times and from this snowfield one or more glaciers descended northwards towards Batote. The entire Patni Top area has at present the topography of a big cirque now breached by a couple of small streams.

Niobium–Zirconium–Thorium–Uranium and Rare-Earth Minerals from the Pegmatites of South Harris, Outer Hebrides

DURING a recent examination of some of the pegmatites in the Lewisian rocks of South Harris a suite of rare minerals was found which may stimulate further research into the numerous, but somewhat neglected, pegmatite occurrences in other parts of the Lewisian of north-west Scotland.

References to the South Harris pegmatites have been made from time to time[1–4], and Holmes, Shillibeer and Wilson[5] estimated the age of the potash–felspars from the Chiapaval and Roneval pegmatites by the potassium–argon method and found them to be 1,110 ± 70 million years, and 1,140 ± 70 million years, respectively.

In the earlier part of the Second World War, the Chiapaval pegmatite near Northton and the Sletteval pegmatites east of Roneval were opened out and quarried for potash–felspar on a considerable scale. These large quarries attracted our interest, and a search for rare minerals was made.

The Chiapaval pegmatite vein, which stretches for a mile, and in places is up to 80 ft. thick, consists of microcline, albite and quartz, with a subordinate amount of muscovite as the major mica constituent. Of the minor minerals, topaz, beryl, black-tourmaline and garnet have been previously recorded[1,4]; the latter mineral seems to be quite abundant locally and was found to contain some 20 per cent of manganese monoxide. In addition, the following minerals have been found: columbite (approximately 60 per cent of niobium pentoxide), thorite, uraninite, kasolite (a hydrated uranium-lead silicate), a mineral with an X-ray diffraction pattern almost identical with kasolite, but predominantly a thorium-lead silicate, betafite, zircon, monazite, allanite, and gahnite (a zinc-spinel).

No zoning on a large scale is apparent in the Chiapaval pegmatite: on a small scale, however, microcline–albite–quartz zoning does occur. The rare minerals are not confined to any particular zone or paragenesis, and columbite, for example, was observed in association with microcline, albite, muscovite and quartz, and even at times enclosed in the manganese garnet. The association garnet–gahnite–columbite is quite common.

The main Sletteval pegmatite quarries, east of Roneval, were examined in some detail; but apart from apatite no unusual minerals were observed.

A pegmatite north-east of Sletteval, near Loch a' Sgurr, contained numerous magnetite aggregates, associated with a greenish-yellow mica, which were found to be quite radioactive. Laboratory investigation showed that this pegmatite contained uraninite, thorite, monazite, uranophane and epidote, together with metamict zircon and allanite, and minor spessartine and pyrites. Under the binocular microscope, all these minerals can be seen closely associated with the magnetite.

The pegmatites of the area fall into two major groups: (*a*) those with muscovite as the dominant mica; (*b*) those containing biotite mica, magnetite and only minor muscovite, which generally show more radioactivity than the former.

BIOCHEMISTRY and PHYSIOLOGY

Presence of Griseofulvin in Hair of Guinea Pigs after Oral Administration

GENTLES[1] has found that oral administration of griseofulvin to guinea pigs previously infected with either *Microsporum canis* or *Trichophyton mentagrophytes* arrests the progress of the fungal disease and prevents the highly inflammatory reaction normally encountered in untreated animals. Histological examination showed that most of the hair follicles and most of the lower portions of hair-shafts were free from dermatophytes after a few oral doses of the antibiotic. The hyphal tips of the fungi were sometimes malformed and in that way reminiscent of the effect of griseofulvin on other susceptible fungi.

These findings can be explained by postulating that griseofulvin is deposited in the keratinous layer of the epidermis and penetrates into the hair follicle, where it is somehow incorporated into the newly formed keratin of emerging hair-shafts. The latter should thus contain a band of resistant keratin from which it might be possible to recover griseofulvin.

To test this theory, bulked hair from several untreated guinea pigs and from animals that had received 23 consecutive daily oral doses of 30–40 mgm./kgm. were extracted and the purified extracts were subjected to bio-assay against *Alternaria solani*, using a modification (Napier, E. J., and Rhodes, A., personal communication) of the *Botrytis allii* hyphal curling assay[2]. The bio-assays were carried out by Mrs. E. J. Napier, of Glaxo Laboratories Ltd.

Since the bio-assay is affected by the presence of some contaminants, a fairly elaborate purification procedure was used. The animals were kept in individual cages with wire grid bases, to avoid contamination with griseofulvin from urine or fæces, and were closely clipped before treatment, to ensure a high concentration of griseofulvin in the hair. At the end of the treatment, 7·5-gm. portions of hair from treated and untreated animals were washed by stirring for half an hour with 450 ml. water and then similarly stirred and filtered three more times. The first three filtrates (*a*) were combined, (*b*) the fourth was kept separate. The hair was then extracted by refluxing four times for half an hour with 250-ml. portions of methanol. The first three filtrates from these extracts (*c*) were combined and (*d*) the fourth was kept separate. The aqueous filtrates (*a* and *b*) were extracted separately with half-volumes of light petroleum (60°–80° C.). This removes undesirable lipoid matter, but extracts some griseofulvin also, which was recovered by re-extracting the petroleum layers with equal volumes of 50 per cent aqueous methanol. After the methanol had been removed from these phases by distillation under reduced pressure, the aqueous residues were bulked with the corresponding main aqueous fractions, each of which was then extracted with benzene (3 × quarter-volumes). The two benzene extracts were dried over sodium sulphate, concentrated to small bulk under reduced pressure and passed through alumina columns (3*g*, 'Woelm acidic'). Development with benzene (about 200 ml.) having removed further impurities, the griseofulvin was eluted with 1 per cent ethanol in benzene. The eluates were evaporated to dryness under reduced pressure and were then ready for bio-assay.

The two methanolic filtrates (*c* and *d*) were extracted with half-volumes of light petroleum, which was discarded. The methanol solutions were concentrated to small bulk with the addition of water, distillation being continued until all methanol had been removed. The aqueous solutions were extracted with benzene and the benzene extracts processed further, as described above. The results of the eight bio-assays are shown in Table 1.

From 1 gm. hair of the treated animals, between 5 and 6 μgm. griseofulvin were obtained, about half

Table 1. GRISEOFULVIN CONTENT OF GUINEA PIG HAIR

Fraction	Total griseofulvin (μgm.) in 7·5 gm. hair:	
	Control	Treated
a	0	21
b	0	0
c	0	20
d	0	0·8

of it being extractable by cold water. It is not at present clear whether perhaps this portion was excreted through the skin and only adhered to the hair, the other half having been deposited in the hair keratin. Whatever the exact mechanism, it seems fairly certain that the eradication of dermatophytic infections by griseofulvin is due to its incorporation somehow in keratinous tissues.

Effects of Deficiency of Pantothenic Acid on Oxygen Poisoning in the Rat

IT has been known for many years[1] that a close connexion exists between pantothenic acid and the suprarenal glands, atrophy of which may result from a deficiency of pantothenic acid. More recently, Hurley and Morgan[2], arguing that animals in the final stages of pantothenic acid deficiency should behave as though adrenalectomized, showed that rats on such a diet were less resistant to the stress of anoxia than were normal controls.

It has, however, been shown that when the 'stress' is exposure to pure oxygen under high pressure, adrenalectomized rats fare better than do normal animals[3–5]. I found[6] that the variability in the time of appearance of nervous system effects in oxygen poisoning was very great in adrenalectomized rats and could not be correlated with the presence of small amounts of residual cortical tissue. Since it seemed reasonable to assume that a dietary deficiency would affect all susceptible tissue, irrespective of its site in the body, it followed that a pantothenic acid deficiency might well dispose of aberrant cortical tissue in a way that operation could never do. If such deficient animals were at least as resistant as operated animals and showed less variability of response, the result would tend to confirm the hypothesis that in operated animals the variability was in fact due to aberrant cortical tissue.

A series of experiments was carried out to test the effects of exposure to pure oxygen under a pressure of 6 atm. on rats reared on a pantothenic acid-deficient diet. Eight litters of eight rats, four of each sex, were used. The basic diet was that already described by me[7]. Appropriate vitamin supplements other than pantothenic acid were added to it, and it was fed to the mothers from 12 days before weaning. On weaning, the young rats were divided into 4 groups as follows: *A*, rats fed the deficient diet *ad lib.*; *B*, rats given the basic diet with vitamin supplements, including pantothenic acid (that is, the control diet), and pair-fed within litters with those of *A*; *C*, rats from which both adrenals were removed four days before exposure to oxygen and fed the control diet *ad lib.*; *D*, rats fed the control diet *ad lib.*

At the age of approximately 8 weeks the rats were exposed to oxygen under 6 atm. in a way already described[6]. Four male and two female rats in group *A* died before exposure to oxygen.

The mean times to the onset of severe poisoning, with standard errors, were, for the four groups, as follows: *A*, 49·75 ± 4·46 min.; *B*, 37·50 ± 1·94 min.; *C*, 45·12 ± 2·78 min.; *D*, 30·50 ± 1·09 min. Both the deficient and the operated rats (*A* and *C*) were more resistant than groups *B* and *D*, although, of these, the pair-fed rats *B* were more resistant than the controls fed *ad lib.* (*D*). There was no significant difference in resistance between groups *A* and *C*. Groups *A* and *C* were more variable than group *B*, itself more variable than the controls fed *ad lib.* (*D*).

The effects of pantothenic acid deficiency on oxygen poisoning thus resemble those of adrenalectomy. The problem of the variability of response in these animals remains unsolved. That the diet was effective was shown by the six deaths, by greying of the fur and by the relative failure of the rats to grow; but there was no evidence that time to onset of severe poisoning was related to body-weight. There was no relationship between weight of suprarenal tissue and time to onset of severe poisoning in group *A*, but three of the four most resistant animals had glands which were obviously hæmorrhagic. It is not clear how to determine precisely, in terms of cortical function, the response of individual rats to the pantothenic acid-deficient diet, and thus one source of variability may have been substituted for another. Or it may be that the variability is due to a highly complex relationship between suprarenal cortical function and response to exposure to oxygen under high pressure.

I am indebted to Mr. R. M. Cormack of the Department of Statistics, University of Aberdeen, for help in the design and analysis of the experiments.

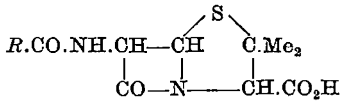
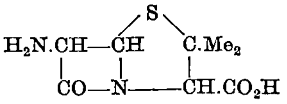
Synthesis of Penicillin : 6-Aminopenicillanic Acid in Penicillin Fermentations

THE work reported here stemmed from the experiments described in an earlier communication[1] on *p*-aminobenzylpenicillin, in which discrepancies were observed between chemical and biological methods of penicillin assay when a precursor was omitted from penicillin fermentations.

The various penicillins (formula I) may all be regarded as acyl derivatives of a common parent amine, 6-amino-penicillanic acid (formula II: for nomenclature see Sheehan *et al.*[2]). We wish to report the isolation of pure 6-amino-penicillanic acid from penicillin fermentations carried out in the absence of added side-chain precursor, the culture used being an isolate from *Penicillium chrysogenum* *W*.51.20.



(I)



(II)

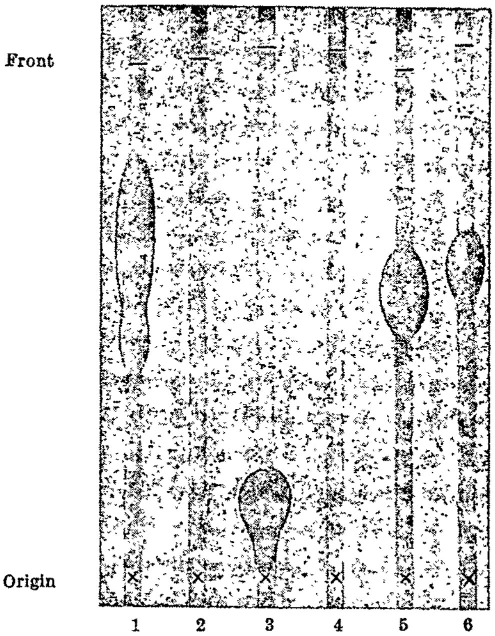


Fig. 1. Chromatograms of fermentation liquors. 1, Filtrate of fermentation carried out in the absence of side-chain precursors; 2, filtrate as (1) after extraction with butyl acetate at *p*H 2·0; 3, as (2) but the chromatogram sprayed with aqueous sodium bicarbonate and an acetone solution of phenylacetyl chloride before developing on the seeded agar plate; 4, solvent-extracted filtrate as (2) treated with penicillinase before chromatography and then sprayed with the solutions of sodium bicarbonate and phenylacetyl chloride as in (3); 5, solvent-extracted filtrate, as (2), treated with sodium bicarbonate and phenylacetyl chloride before chromatography; 6, penicillin *G*. Solvent: butanol/ethanol/water, 40 : 10 : 50, top layer; Whatman No. 1, running time 15 hr.

The presence of (II) was first indicated when such a fermentation liquor, after removal of natural penicillins by solvent extraction at low *p*H, was treated with an excess of phenylacetyl chloride in the presence of a weak base such as sodium bicarbonate. This resulted in the formation of an antibiotic substance which was readily destroyed by penicillinase and which behaved similarly to penicillin *G* on paper chromatograms. Similarly, reaction with phenoxyacetyl chloride resulted in the formation of an antibiotic resembling pencillin *V* in its stability in acid solution as well as its behaviour on paper chromatograms. The reaction with phenylacetyl chloride in the presence of sodium bicarbonate was readily adapted to the detection of (II) on paper chromatograms (Fig. 1) which were sprayed with the appropriate reagents before plating on agar seeded with a sensitive bacterium in the usual way. This conversion of (II) to benzylpenicillin on paper strips also provided a convenient method of assay, being similar to the well-known paper disk method.

Pure crystalline 6-aminopenicillanic acid, details of the isolation of which will be reported at a later date, had m.p. 208–209° C. (decomp.) (found: C, 44·6; H, 5·7; N, 13·1; S, 14·1 per cent; $C_8H_{12}O_3N_2S$ requires C, 44·4; H, 5·6; N, 13·0; S, 14·8 per cent). Phenylacetylation and subsequent biological assay on paper as outlined above gave 2,740 units of benzylpenicillin per mgm. of starting material (theory 2,752 units/mgm.). 6-Aminopenicillanic acid itself possesses definite antibacterial properties, but these are mostly of a much lower order than those of benzylpenicillin, and the spectrum is of a different type. It is destroyed by penicillinase (*Bacillus cereus* broth filtrate) but at a much slower rate than is benzylpenicillin. Like the penicillins it is rapidly decomposed by strong alkali, but as would be expected from its structural inability to undergo rearrangement to a penillic acid, it is relatively stable to acids. The compound is itself a surprisingly strong acid, the isoelectric point being about 4·3.

Chemical evidence supporting the structure (II) has been obtained by treatment of the substance with ethyl chloroformate to give a crude N-carbethoxy derivative (I; R = EtO) which was degraded by the general method of Dutcher *et al.*[3] to N-carbethoxyaminoacetaldehyde 2 : 4-dinitrophenylhydrazone (51 per cent overall yield), bright yellow micro-needles from alcohol, m.p. 174–175° C., not depressed by admixture with a specimen synthesized from aminoacetal (found: C, 42·2; H, 4·2 per cent; $C_{11}H_{13}O_6N_5$ requires C, 42·4; H, 4·2 per cent).

Furthermore, the benzylpenicillin which had been prepared by phenylacetylation of (II) was isolated as the N : N′-dibenzylethylenediamine salt, which after crystallization from acetone had m.p. 114–115° C., not depressed by admixture with an authentic specimen[4] (found: C, 59·4; H, 6·8; N, 9·0; S, 6·5 per cent; calc. for $C_{48}H_{56}O_8N_6S_2.3H_2O$: C, 59·8; H, 6·5; N, 8·7; S, 6·7 per cent). A portion of this same phenylacetylation product was degraded to benzylpenilloaldehyde, which was isolated as the 2 : 4-dinitrophenylhydrazone, m.p. 196° C., not depressed by admixture with an authentic specimen[3].

Various authors have expressed the view that the last stage in penicillin biosynthesis is the introduction of the acyl side-chain[5]. Our isolation of 6-aminopenicillanic acid is consistent with this view, but does not preclude the possibility of it arising during fermentation, either as an alternative metabolite or by enzymatic hydrolysis of a penicillin[6]. The substance is nevertheless a most useful chemical intermediate for the preparation of new penicillins and related compounds which are not easily accessible in other ways. The possible therapeutic usefulness of such derivatives is being investigated in these Laboratories (patent application pending, 1957).

We wish to thank Prof. E. B. Chain, Dr. A. H. Cook and Sir Ian Heilbron for helpful discussions and the Directors of Beecham Research Laboratories for permission to publish this communication.

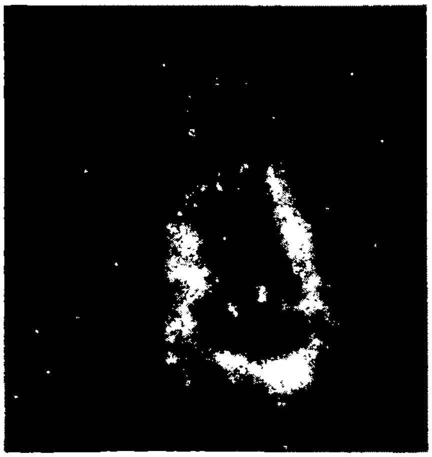

Fig. 2. 8-μ cold microtome section of mouse kidney, 18 hr. after intraperitoneal injection of ovalbumin labelled with a fluorescent dichloro-triazinyl dye. (× 1,100)

The labelling of proteins with reactive dyes is simple and offers considerable advantages over current methods of conjugating proteins through azo[5] and ureido[6] linkages. In a series of preliminary tests with fluorescent or coloured dyes containing other reactive groups (sulphon-β-chloroethylamide, sulphon fluoride, thiocyano, chloroacetylamino, γ-chloro- β-hydroxy-propyl) the superiority of the dichloro-triazinyl group appears to be established. These studies are being continued and extended.

Reversal of Antibiotic Action of Cycloheximide (Actidione) by Bivalent Metal Ions

Cycloheximide, an antibiotic with selective inhibitory effect on many fungi[1,2] but inactive against bacteria, has received increased attention during recent years, but few reports are concerned with its mode of action. Cycloheximide inhibits aerobic utilization of many intermediates of carbohydrate metabolism by *Tetrahymena pyriformis*[3], and it is active against higher plants[4]. Kerridge[5] has observed that fungistatic doses of cycloheximide (0·5–1·0 μgm./ml.) have no marked effect on fermentation and respiration of *Saccharomyces mandshuricus*, but synthesis of protein and deoxyribonucleic acid is completely blocked. On the other hand, Greig *et al.*[6] have recently announced that in the case of *Saccharomyces cerevisiae* the same antibiotic shows an inhibitory effect on fermentation.

This communication presents the results of a study of the inhibitory action of cycloheximide on growth and respiration of a sensitive strain of *Candida krusei* and a resistant strain of *Candida albicans*. Previous authors employed agar plate techniques for measurement of growth; in the present work growth was estimated turbidimetrically. Cultures were incubated for 22 hr. with forced aeration at 28° C. in a liquid medium containing glucose and mineral salts.

The results of experiments on growth show that 0·5 μgm./ml. of cycloheximide has a marked antibiotic effect while 2 μgm./ml. inhibit completely the multiplication of *C. krusei*. The growth of the resistant *C. albicans* was not altered by concentrations of antibiotic up to 100 μgm./ml. The activity of antibiotic remained unchanged when ammonium sulphate in the medium was replaced by other nitrogen sources, such as amino-acids, peptides and protein hydrolysates. Curiously enough, the only exception was peptone which, in a concentration of 1 per cent, almost completely suppressed the inhibitory action of cycloheximide. The degree of inhibition depended on the origin of the peptone employed and was due not to the organic components but to iron. When the heavy metals in peptone were precipitated by hydrogen sulphide the reversal of inhibition did not occur; when ferrous iron alone was added to the mineral medium with inorganic source of nitrogen, the inhibitory effect of cycloheximide was suppressed.

The reversal of inhibitory activity was also demonstrated in manometric experiments with washed suspensions of *C. krusei*. Cycloheximide at a concentration of 0·5 μgm./ml. caused 40 per cent inhibition of the rate of oxidation of glucose by intact cells. In the presence of 2×10^{-4} *M* $FeSO_4.7H_2O$ and 0·5 μgm./ml. of cycloheximide the respiration was even faster than in the control without antibiotic. Manganese or zinc, like iron, antagonized the inhibitory effect of antibiotic; calcium, magnesium or cadmium were less active and copper had no detectable effect. Respiratory activity of washed cells of *C. albicans* was not influenced by cycloheximide.

These observations suggest that cycloheximide forms chelates with bivalent metals and that these complexes are antibiotically inactive. This phenomenon of chelate formation is not unique among antibiotics, and the subject has been well summarized in a review by Weinberg[7]. He, as well as Whiffen[2], did not report any influence of metals in the case of cycloheximide; but Greig *et al.*[6] observed potentiation of the inhibitory effect of this antibiotic on fermentation by *Saccharomyces cerevisiae*. This apparent discrepancy concerning the mode of action of metals on antibiotic potency of cycloheximide seems to be due not only to the use of different organisms but also to different criteria and methods employed.

Details of these experiments will be published elsewhere.

Determination of Nitrogen in Proteins by means of Indanetrione Hydrate

THE determination of nitrogen in organic substances has been performed by either of the well-established methods, namely, one attributed to Dumas or the other first described by Kjeldahl. These methods require approximately 300 μgm. of nitrogen for accurate determination. The method to be described requires much less material, and compares favourably in accuracy with these standard methods. The sample is decomposed by digestion in sulphuric acid, and the ammonia is determined quantitatively by means of indanetrione hydrate.

The sample (for example, 0·05–0·10 ml. serum) is digested in 0·5–1·0 ml. sulphuric acid to which is added 3–5 mgm. of a mixture of copper sulphate (microanalytical reagent), potassium sulphate (microanalytical reagent), mercuric oxide (laboratory grade) and selenium (5 : 15 : 5 : 1 parts by weight respectively). The sample is heated in a standard Kjeldahl flask for 45 min., when it should have cleared. If the acid digest is not clear after 45 min., the flask is cooled, 0·2 ml. of hydrogen peroxide solution (100 vol. B.D.H., microanalytical reagent) is added drop by drop and the contents of the flask are re-heated. The solution becomes clear immediately and the heating is continued for 2 hr.

The digested sample is dissolved in 0·4 M sodium citrate buffer solution pH 5·0 (25 ml. buffer solution for 0·5 ml. sulphuric acid : 50 ml. buffer solution for 1·0 ml. sulphuric acid). An aliquot, normally 0·5 ml., of this solution, diluted further if necessary with buffer solution to make 2·0 ml., is mixed with 2·0 ml. of a 2 per cent indanetrione hydrate solution. (2·0 gm. indanetrione hydrate : 50 ml. methyl 'Cellosolve' : 25 ml. 4·0 M sodium acetate buffer solution pH 5·5 (544 gm. sodium acetate trihydrate + 100 ml. glacial acetic acid per litre) : 25 ml. water : 0·08 gm. stannous chloride dihydrate (analytical reagent).) The mixture is heated in a water bath at 100° C. for 30 min., cooled and diluted with 6 ml. of a solution of ethanol/water (1 : 1 by volume).

When determined in a Uvispek spectrophotometer, a solution containing 0·4 μM of ammonia (= 5·6 μgm. nitrogen) has an optical density of 0·805 (±0·008) for 1 cm. path-length at a wave-length of 570 mμ. The optical density of the control solution, that is, 1·0 ml. sulphuric acid (microanalytical reagent) diluted in the same manner, varies between 0·045 and 0·060.

Column 1 of Table 1 shows typical analyses of a serum from a normal rhesus monkey performed by the indanetrione hydrate method. Column 2 shows analyses of the same serum by the standard micro-Kjeldahl method.

Table 1

Indanetrione hydrate	Micro-Kjeldahl
11·3 mgm. N per ml.	11·3 mgm. N per ml.
11·3	11·4
11·4	11·3

The method has been used for routine purposes and is found to be more reliable than the standard micro-Kjeldahl method. The aliquot, examined in triplicate if necessary, contains only one-fiftieth or one-hundredth part of the original nitrogen. Work is in progress to apply this method to the quantitative determination of nitrogen in other nitrogenous compounds following their digestion in sulphuric acid.

The indanetrione hydrate may be purified without loss by the method already described[1]. The presence of traces of cations in the digest solution, due to the catalyst, does not affect the colour development (cf. Meyer and Riklis[2]) during the reaction between the ammonia and the indanetrione hydrate. Wherever possible, analytical reagents are used and all solutions are prepared with conductivity water obtained by de-ionizing once-distilled water[3]. In our experience the analytical reagent most likely to produce high values of optical density with the control solution is sodium acetate: but this compound may be easily purified by re-crystallization from ethyl alcohol to yield satisfactory values of optical density with the control solution.

Replacement of Thiamine as a Growth Factor for *Mycobacterium butyricum*

THIAMINE is recognized as a growth factor for many micro-organisms. Some micro-organisms require the presence of the whole thiamine molecule whereas others are able to synthesize either the pyrimidine or thiazole moieties. In some instances, cells are unable to use either component, but if supplied with the two fragments can combine the two into the complete molecule. Pyrithiamine (1-[(4-amino-2-methyl)-5-pyrimidylmethyl]-2-methyl-3 (α-hydroxyethyl) pyridinium bromide) is a thiamine analogue in which a pyridine ring replaces the thiazole moiety. This analogue has an anti-thiamine effect in some micro-organisms, and in others it can replace thiamine by acting as a source of the pyrimidine ring[1,2].

Thiamine is required for the growth of *Mycobacterium butyricum* in chemically defined media[3]. This requirement has been examined by growing *M. butyricum* (No. 337, National Collection of Type Cultures, Lister Institute, London) on a synthetic medium containing inorganic salts with glycerol as a carbon source and ammonium sulphate as a nitrogen source. To this medium was added thiamine hydrochloride, 4-amino-5-aminomethyl 2-methyl pyrimidine 2 hydrochloride, 5-(2-hydroxyethyl) 4-methyl thiazole, or pyrithiamine. The medium was sterilized by autoclaving at 15 lb. for 15 min. The flasks (500 ml.) containing 100 ml. of medium were inoculated with a washed suspension of cells (0·4 mgm. dry wt.) and the cultures incubated aerobically at 38° for nine days. Growth was estimated by filtering off the cells, washing well with distilled water and drying at 105° in weighed crucibles.

Only a slight growth was observed in the absence of thiamine or with the thiazole fragment (Table 1). Good growth occurred with thiamine, with the pyrimidine moiety, with the pyrimidine plus thiazole moieties, or with pyrithiamine. Since the pyrimidine fragment seems to be essential for growth, it was considered possible that pyrithiamine was exerting its effect due to hydrolysis on autoclaving. This was tested by adding to the growth medium pyrithiamine sterilized by autoclaving or by filtering through a glass filter (porosity 5), or by adding directly from its bottle to the sterile medium. No difference was noted in the growth response to autoclaved, filtered or unsterilized pyrithiamine.

These results demonstrate the inability of *M. butyricum* to synthesize the pyrimidine moiety of thiamine at a sufficient rate to promote normal

Table 1. THE REPLACEMENT OF THIAMINE AS A GROWTH FACTOR FOR *Mycobacterium butyricum*

Addition to medium	Concentration of addition (μgm./100 ml.)	Bacterial growth (mgm. dry weight)
No addition	—	20
Thiamine	200	114
Thiamine	1,000	119
Pyrimidine fragment	100	101
Pyrimidine fragment	500	106
Thiazole fragment	100	20
Thiazole fragment	500	24
Pyrimidine plus thiazole fragments	100 500	102 110
Pyrithiamine	200	117
Pyrithiamine	1,000	122

growth. Presumably the bacteria can split pyrithiamine and utilize the pyrimidine portion. Martin[4] has reported similar findings with *Nocardia corallina*, an organism related to the *Mycobacteria*, and Lutz[5,6] has shown that the thiamine requirement of *M. phlei* and *M. paratuberculosis* could be replaced by the pyrimidine moiety for the former and by the pyrimidine moiety or pyrithiamine for the latter organism.

Aminopeptidase Activity in Cancer Cells

THE enzyme, aminopeptidase, was included in an investigation on histochemically demonstrable enzyme activities in human pathological lesions. This enzyme was demonstrated by Burstone's method[1] except that cryostat sections were used which were fixed for 5 min. in acetone.

Some observations on aminopeptidase activity in tumours have appeared[2,3]. The authors of these publications mention the high aminopeptidase activity in the stroma around invading tumour cells; but they saw only little activity in the tumour cells.

At present, we have investigated the aminopeptidase activity in about sixty human neoplasms, surgically removed. We can confirm the observations on aminopeptidase activity in some parts of the stroma around the tumour cells. This was especially the case in epidermoid carcinoma, for example, of the lung (eight cases). However, the most striking observation we made was the very high aminopeptidase activity in the tumour cells in each of four cases of gastric carcinoma and in two cases of carcinoma of the bile ducts. After a very short incubation (5 min.) of the acetone-fixed sections in the substrate, activity was demonstrated by the brilliant red coloration developed.

The gastric carcinomas were of different types. The first case was an anaplastic carcinoma of the stomach with metastases in the regional lymph nodes. In the sinus of these lymph nodes many tumour cells of the signet cell type could be seen. In the anaplastic cells of the primary tumour as well as in the signet cells of the lymph nodes a high aminopeptidase activity was observed (Fig. 1).

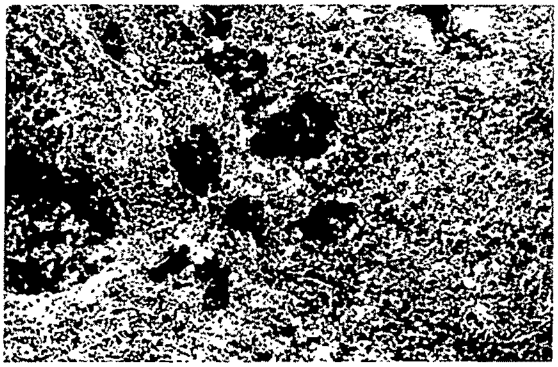

Fig. 1. Groups of signet cells in a lymph node with a high aminopeptidase activity

In the second operation specimen a well-differentiated adenocarcinoma infiltrated the muscle layers of the stomach wall. These tumour cells all showed high aminopeptidase activity in their luminal borders (Fig. 2).

In the third case of a poorly differentiated adenocarcinoma, we observed a high aminopeptidase activity throughout the protoplasm of many tumour cells.

The fourth gastric carcinoma was obtained from an autopsy. In the stomach an ulcerating carcinoma was found, about 2 cm. in diameter. In the lymph nodes the tumour cells showed high enzyme activity.

In some cases of atrophic gastritis combined with a peptic ulcer the epithelial cells show no aminopeptidase activity except for some islands of positive cells of the surface epithelium and in the crypts. These islands are more numerous in the prepyloric region, while in the duodenum and small intestine all epithelial cells show a high aminopeptidase activity along their luminal border.

In a peptic ulcer, aminopeptidase activity was only seen in the granulation tissue of the bottom.

In a normal human stomach no enzyme activity was found in the epithelial cells. In normal lymph nodes and in lymph nodes with proliferation of the reticulum cells only some scattered reticulum cells with aminopeptidase activity were seen. This activity is not as high as in the cells of the gastric cancer; moreover, no groups of positive cells were seen in these lymph nodes.

Both carcinomas of the bile duct were of the anaplastic type. Most of the tumour cells stood out clearly by their high enzyme activity. In the

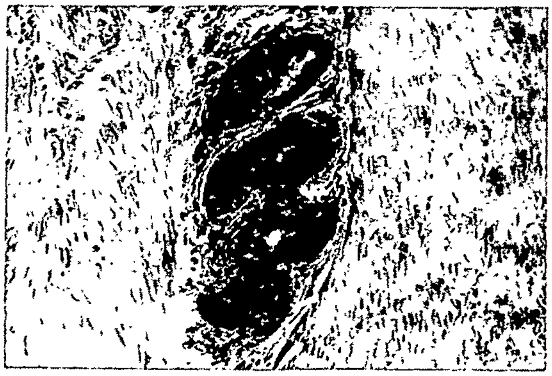

Fig. 2. Aminopeptidase activity in luminal border of tumour cells of an adenocarcinoma

normal epithelium of the human gall bladder and bile ducts there is high aminopeptidase activity in the luminal borders of the cells. Hitherto none of the other tumours has shown aminopeptidase activity.

On the basis of these observations we think that it is worth while to apply this histochemical method for aminopeptidase activity in fresh surgical specimens: (1) in lymph node biopsies with metastatic tumour cells, to investigate the possibility of gastric or bile duct origin; (2) during operations for gastric and bile duct carcinoma, to detect tumour cells in regional lymph nodes and surgical margins.

Recording Inhibition and Excitation in the Cat's Retinal Ganglion Cells with Intracellular Electrodes

In the light-adapted state, the receptive fields of retinal ganglion cells in the cat consist of excitatory and inhibitory areas. Thus predominantly excitatory and inhibitory pathways converging on a ganglion cell can be stimulated selectively[1] and thereby the mechanism of excitation and inhibition can be studied. It has recently become possible to record from retinal ganglion cells with intracellular leads for short periods[2]. In the present study, penetrations into cells were fairly frequent; but most cells gave injury discharges and their membrane potentials declined within several minutes. However, intracellular records from some ganglion cells were recorded with stable membrane potentials of 50–70 mV. for as long as 20 min. Discharge patterns were similar to those obtained during extracellular recordings.

The following typical changes were seen in the membrane potential and in the discharge patterns of ganglion cells in the light-adapted state. If in an 'on'-centre receptive field a light spot was shone in the centre of the field, a maintained graded depolarization was set up, accompanied by an increase in frequency of impulses (Fig. 1*A*). The magnitude of the maintained depolarization as well as the discharge-rate were graded according to the strength of illumination. When the light was turned off the membrane potential and discharge frequency gradually returned to original levels. If an annular-type stimulus was used, throwing light only on the outer portion of the same receptive field, the maintained background activity was suppressed. At the same time the membrane potential of the cell was increased (Fig. 1*B*). As the light was turned off, there was a further increase of the membrane potential, followed by depolarization and an off discharge. In Fig. 1*C* the entire receptive field was illuminated, resulting in an interaction between the excitatory and inhibitory portions. The excitatory component predominated, but was much less effective than if the centre alone (as in Fig. 1*A*) was illuminated. Thus stimulation of the entire receptive field caused less impulse activity and less membrane depolarization than illumination of the central portion alone. A marked increase in membrane potential and inhibition of impulse activity occurred as the light stimulus was turned off.

Quite frequently an impaled ganglion cell stopped firing impulses a few minutes after penetration, presumably due to injury by the electrode. But the maintained decrease or increase in the membrane potential could still be observed with appropriate illumination, indicating that these slow potential changes were not dependent on the propagated impulse mechanism.

A few intracellular recordings were obtained from the retinal, presumably unmyelinated, portion of axons of ganglion cells. Membrane potentials were near 50 mV., and the axons were identified by the following criteria. The centre of the receptive field

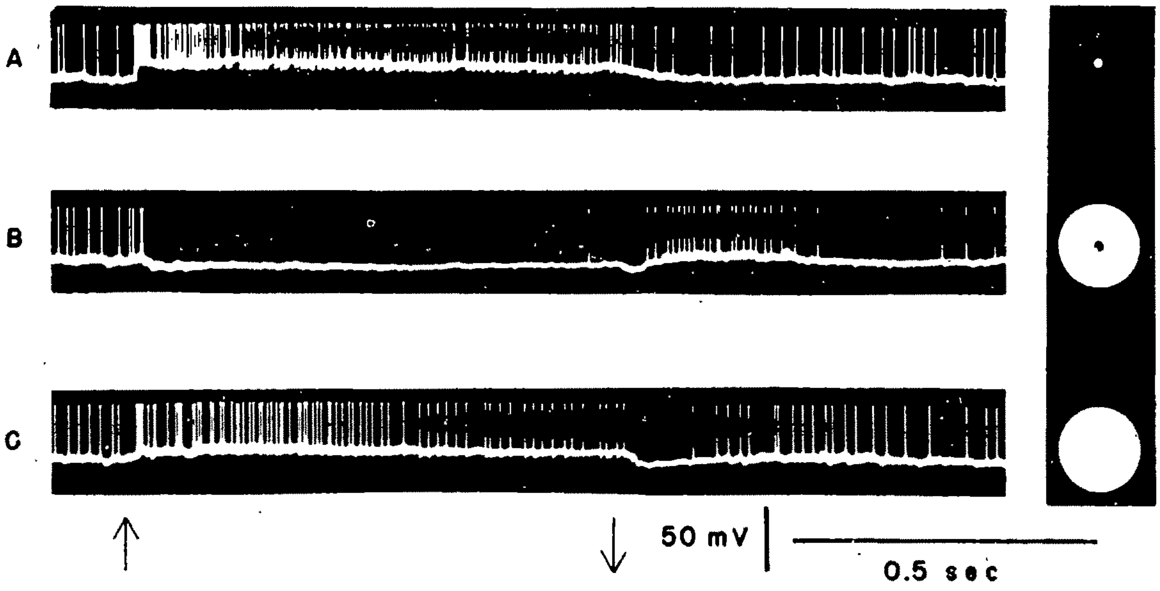

Fig. 1. Intracellular recording from retinal ganglion cell. Membrane potential about 65 mV. Period of illumination marked by arrows. Right, illuminated area marked white. *A*, small light spot of 1° (0·25 mm.) diameter; *B*, annular stimulus, outer diameter 12° (3 mm.) (central area of 1° is not illuminated); *C*, entire receptive field illuminated. Background illumination 0·34 log m.c. Stimulus intensity about 1·85 log m.c.

of such a fibre was some distance from the electrode tip toward the periphery of the retina. The typical slow changes of ganglion cells were absent, the potentials rose sharply and were all or none. Further, there was no sign of synaptic noise which was always present in ganglion cells.

The present observations may be compared with those in a variety of nerve cells. Thus, Eyzaguirre and Kuffler[3], recording from the cell body of the stretch receptor of crayfish, showed corresponding excitatory and inhibitory changes which determined the discharge frequency. Further, Hartline, MacNichol and Wagner[4] and Fuortes[5], leading from the eccentric cell in the *Limulus* eye, described a similar graded depolarization during illumination which was directly related to the discharge frequency. Corresponding slow potentials, both with excitation and inhibition, have been reported by Kolmodin and Skoglund[6] in the motoneurons and interneurons of the cat's spinal cord. The cortical cells studied by Phillips[7] also had similar slow potentials.

The retinal ganglion cells are the final points of convergence from the neuronal network of the receptive fields, which can extend over an area up to several mm. in diameter. The cells can integrate the excitatory and inhibitory synaptic influences in terms of slow changes in their membrane potential. Presumably, these in turn control the discharge frequencies of the optic nerve fibres.

Bacterial and Testicular Hyaluronidase

IN papers from this laboratory, the actions on dermal connective tissue[1,2] and on ocular structures[3,4] of different kinds of hyaluronidase have been studied. In these experiments, 'Hyason', manufactured by Organon, Oss, Holland, was used as a source of staphylococcal hyaluronidase. This is also preparation *D* of Chauncey *et al.*[5].

We have recently been informed that batches of 'Hyason' released after January 29, 1958, contain testicular instead of bacterial hyaluronidase and we write this communication in order to prevent confusion arising from the change in composition. The manufacturer keeps a stock of the old preparation, and samples are available for research purposes.

Excitation of the Squid Axon Membrane in Isosmotic Potassium Chloride

THE interesting recent findings in the frog node of Ranvier of an 'action potential' in isosmotic potassium chloride by Müeller[1], and of two stable states in 20–40 m*M* potassium chloride by Stämpfli[2], raise the question as to whether or not similar phenomena are to be found in the squid axon membrane.

I have made a preliminary study of the approximate steady-stage voltage-current relationship for the squid (*Loligo pealii*) giant axon membrane in 0·5 *M* potassium chloride. When the potential was controlled ('*E*-LOC') and varied, a continuous variation of the current is found, including a negative resistance region. The characteristic shape seen in Fig. 1 is typical, although there are some minor variations in the *E–I* curves depending upon the previous potential history and the rate and direction of sweeping. When the current was controlled ('*I*-LOC') and varied the voltage showed the hysteresis loop to be expected about the unstable negative resistance region. This is in complete agreement with Segal's[3] recent finding of two stable potentials for the squid axon membrane in high potassium under current control.

Franck[4] has compiled examples of dynode type characteristics with a negative resistance region which give excitation phenomena. The squid axon membrane in sea water with normal sodium concentration exhibits such a characteristic[5] and gives a normal action potential. Thus, it would also be expected that the squid axon in 0·5 *M* potassium chloride with a similar but displaced characteristic should exhibit excitation under the proper conditions. If the membrane is subjected to a constant hyperpolarizing current, an 'excitation' threshold for superimposed depolarizing current pulses should be found when the net current is less than about 0·15 m.amp./cm.². Fig. 2 demonstrates the threshold and also shows a recovery so that the process may well be called an 'action potential'.

At present, the description of the processes involved in the 'action potential' in 0·5 *M* potassium chloride seems to be as follows: If the squid axon

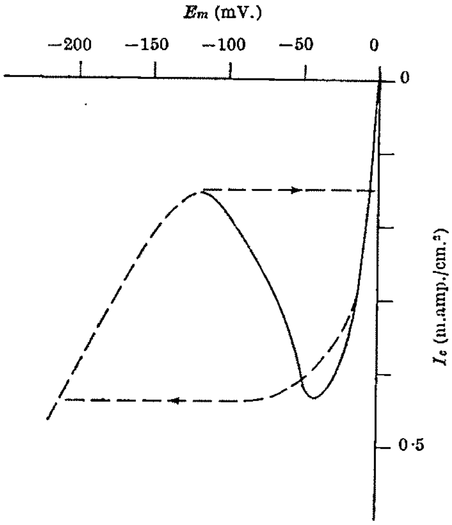

Fig. 1. Voltage-current characteristics of the squid axon membrane in 0·5 *M* potassium chloride. The continuous line was obtained with potential control; the dashed sections with current control. Arrow heads indicate abrupt changes

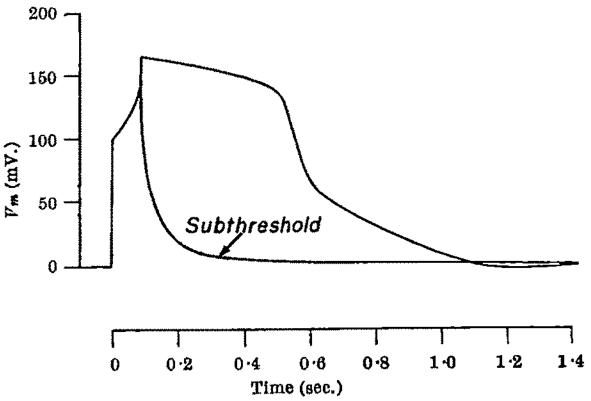

Fig. 2. Time course of an 'action potential' in 0·5 *M* potassium chloride. The membrane was subjected to a constant hyperpolarizing current; additive depolarizing current pulses of about 0·1 sec. of slightly different magnitudes show a threshold

membrane is held near point *A* (in Fig. 3) with a hyperpolarizing current, a pulse of depolarizing current takes the potential up and then along the dashed path at low current; when the pulse is turned off, the membrane potential moves down the right-hand branch of the curve to point *B*. The potential remains in this vicinity until the peak *C* is reduced below the value of the steady current. The potential will then drop back rapidly to point *A*. A possible reason for the shift in the characteristic *E–I* curve and decrease in the peak at *C* is the decrease in potassium concentration in the 'Frankenhaeuser–Hodgkin[6] space' just outside the active membrane. The right-hand branch of the curve through the origin is the characteristic to be expected from 0·5 *M* potassium ion on the Hodgkin–Huxley formulation[7]. The left branch through *A* is probably dominated by the chloride ion conductivity.

The similarities of the frog node[1,8] and squid axon in both normal physiological solutions and isosmotic potassium chloride is highly suggestive of the possibility that similar characteristics are to be found for other excitable membranes with either these or other ions. Outstanding possibilities are chloride ions for *Chara*[9] and barium and strontium ions for crustacean muscle[10].

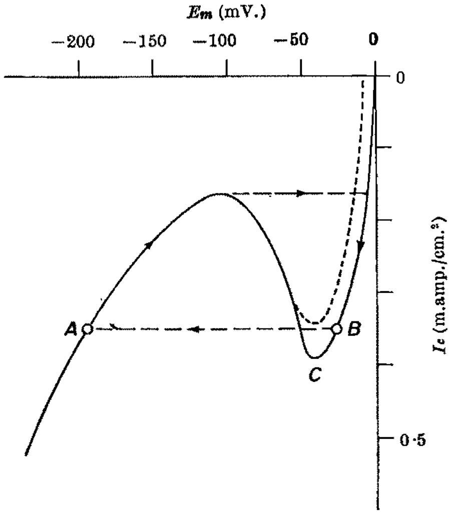

Fig. 3. Trajectories in voltage-current plane which generate an 'action potential'. The dotted line indicates the modification of the branch through the origin when the system remains near the state *B* for about 0·5 sec.

I should like to express appreciation for the co-operation of Drs. K. S. Cole, J. del Castillo and R. E. Taylor in this work, and to the Marine Biological Laboratory, Woods Hole, Massachusetts, for the facilities which made this work possible.

Influence of Temperature and Light on Reproduction in Male Rats

LIGHT has been considered a gonad-stimulating factor[1], which most probably induces its effect via the pituitary in some animals[2]. It has been reported, though, that some animals respond to light only at a certain season of the year and are refractory to it at other seasons[3]. Autumn breeders, on the other hand, as the goat and sheep, breed at the time of diminishing light[4]. This difference could probably be due to variations in environmental temperature. Another point is that light experiments have usually been done with female animals and with birds. The present investigation was planned to study the effects of temperature and light on reproductive performance in male rats.

Forty-eight mature male rats weighing 180–200 gm. were used. They were divided into six groups of eight animals each. Three groups were kept at the temperature of 18 ± 1° C. and the other three groups were kept at 35 ± 1° C.. Of the groups of animals at each of the two experimental temperatures one was exposed continuously to light of a strength of 30 ft.-candles, another group confined to darkness and the third exposed to 12 hr. of light alternating with 12 hr. of darkness. After 12 days the animals were killed by decapitation under light ether anæsthesia. Their blood was collected, allowed to clot and the serum was obtained by centrifugation at 3,000 r.p.m. for 15 min. The serum was kept in the deep freeze until use. The testes and seminal vesicles were weighed with a torsion balance. The testes were fixed with Susa or Zenker's fluid, stained with hæmatoxylin and eosin or Heidenhain's iron hæmatoxylin, then examined histologically. The content of gonadotrophic hormone of the serum obtained from the different groups of rats was determined by the mouse uterus method[5]. Groups of five immature female mice were injected subcutaneously with 0·5 ml. serum every 12 hr., then killed on the fourth day. The weights of mouse uterus were used as a criterion of gonadotrophic hormone-level in the blood of rats.

The groups of rats kept at the lower temperature of 18° C. had heavier testes and presented a normal picture of spermatogenesis, while the rats kept at the temperature of 35° C. showed partial atrophy of the seminiferous tubules and impaired spermatogenesis. Sertoli cells predominated in the picture and there

Table 1. INFLUENCE OF TEMPERATURE AND LIGHT ON TESTES AND SEMINAL VESICLE WEIGHTS OF RATS

Treatment	Body-weight	Testes-weight (mgm./100 gm. body-weight)	Seminal vesicle-weight (mgm./100 gm. body-weight)
Cold—light	219	1,001 ± 16·5	244 ± 35·70
Cold—dark	195	932 ± 62·00	112 ± 25·40
Cold—12 hr. light, 12 hr. dark	185	823 ± 66·10	127 ± 33·40
Temperature—light	194	785 ± 50·7	245 ± 44·2
Temperature—dark	227	841 ± 28·3	180 ± 20·2
Temperature—12 hr. light, 12 hr. dark	233	708 ± 70·0	258 ± 40·90

± Standard error

Table 2. INFLUENCE OF TEMPERATURE AND LIGHT ON SERUM GONADOTROPHIN OF MALE RATS

Treatment	Mouse uterus-weight (mgm./100 gm. body-weight)
Cold—light	165·57 ± 10·11
Cold—dark	154·56 ± 17·10
Cold—12 hr. light, 12 hr. dark	163·14 ± 20·00
Temperature—light	291·53 ± 24·40
Temperature—dark	200·39 ± 8·66
Temperature—12 hr. light, 12 hr. dark	236·94 ± 17·10
Control mice	110·00 ± 9·16

± Standard error.

were a few spermatogonia cells. The gonadotrophic hormone contents of all rats kept at the high temperature were significantly greater than those of their respective groups kept at the lower temperature. This is in agreement with the results obtained in dogs[6]. Such a rise in the level of gonadotrophic hormone is probably due to decreased utilization of the hormone by the refractory testes.

As appears from the accompanying Tables 1 and 2, the rats exposed to light had significantly heavier seminal vesicles than those of the rats confined to darkness. Exposure to light was also accompanied with an increase in the level of gonadotrophic hormone in the blood and increased amount of interstitial tissue in the testes. This gives evidence of increased production and utilization of luteinizing hormone by exposure to light.

The rats exposed to 12 hr. light and 12 hr. dark had heavier seminal vesicles when kept at 35° C. than those of rats kept at 18° C.

It is thus concluded that exposure to light is accompanied by increased production of gonadotrophic hormone with predominance of luteinizing hormone, whereas exposure to cold is accompanied by increased size of the testes and improved spermatogenesis which is apparently due to a rise in level of follicle-stimulating hormone.

HISTOLOGY

A New Type of Chromaffin Cells, probably storing Dopamine

von Euler and Lishajko[1,2] have shown that dopamine occurs in the bovine lung in amounts up to 100 times higher than those of noradrenaline. They also demonstrated that the distribution of dopamine—in contrast to that of noradrenaline—was not related to the adrenergic nerves. On the basis of these findings, they concluded that dopamine in the lung cannot merely be an intermediate metabolite in the synthesis of noradrenaline in the adrenergic axons.

Using a new method for determination of catechol amines, Carlsson and co-workers[3,4] systematically charted the occurrence of these amines in various animals. They found large amounts of dopamine in several tissues in ruminants (cow, sheep, goat) but not in any other animals hitherto studied. In view of the relatively large amounts found, Dr. Carlsson asked us to try to demonstrate the cellular localization of this amine by means of histochemical methods. Since dopamine—like adrenaline and noradrenaline—is easily transformed into insoluble dark pigments by oxidation with potassium bichromate[5], an attempt was made to locate this amine by means of the chromaffin reaction.

The tissues were treated with a potassium bichromate–chromate solution (as described previously[6]) with or without formalin. Adjacent pieces of the tissues were fixed in formalin. The pieces were embedded in 'Carbowax' and sections were mounted unstained or after staining with nuclear fast red (Gurr; 0·03 per cent aqueous solution containing 1·7 per cent aluminium sulphate).

Chromaffin cells differing from the classical chromaffin cells of the sympathetic nervous system (presumably storing adrenaline or noradrenaline; cf. von Euler[7]) were observed in several tissues. They were fairly small (6–10μ), round or somewhat elongated and contained fairly large granules (Fig. 1). Though distinct, the chromaffin reaction was rather weak (yellow to yellow-brown). In contrast to all other chromaffin cells examined (adrenal medulla, chromaffin cells in sympathetic ganglia and carotid

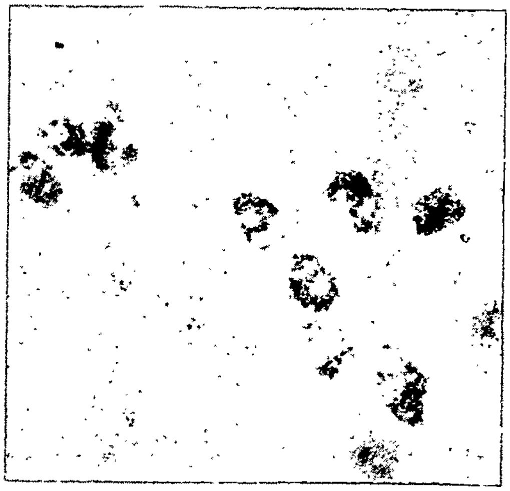

Fig. 1. Chromaffin cells in the visceral pleura from the cow. Fixation in bichromate–chromate–formalin. Staining with nuclear fast red. (× 1,200)

body, enterochromaffin cells, the cells of Adams-Ray and Nordenstam[8]), the cells observed had granules, which after treatment with bichromate–chromate–formalin, stained red within a minute with the nuclear fast red solution used and thus showed up well in the tissues.

That the cells are quite different from the enterochromaffin cells, now generally believed to contain 5-hydroxytryptamine, is evident from the following observations. They show the chromaffin reaction after treatment with bichromate without formalin, but the reaction is negative after fixation in formalin. Furthermore, the formalin-fixed cells do not give any diazo reaction (diazotized safranin[9]).

The cells have so far been observed in tissues from cow, sheep and goat; but not from pig, cat, rabbit, guinea pig or rat. Their distribution does not bear any relation to that of the autonomic nerves. In both these respects they are clearly different from the 'common' chromaffin cells of the sympathetic system and the recently discovered cells of Adams-Ray and Nordenstam.

The distribution of the cells follows closely the content of dopamine in the various tissues. Since this will be described in detail elsewhere, only two illustrative examples are mentioned. In the bovine lung the chromaffin cells are abundant in the connective tissue of the visceral pleura but rather scarce in the intrapulmonary tissue. Such cells are likewise relatively abundant in the cow liver capsule but practically absent in the parenchyma. Dopamine determinations (Carlsson and co-workers) showed that the amine content is substantially higher in the pleura than in the intrapulmonary tissue and that it is high in the liver capsule but very low in the parenchyma.

The presence of a new type of chromaffin cells showing a distribution in close accordance with that of dopamine suggests that the cells are storage structures for this amine.

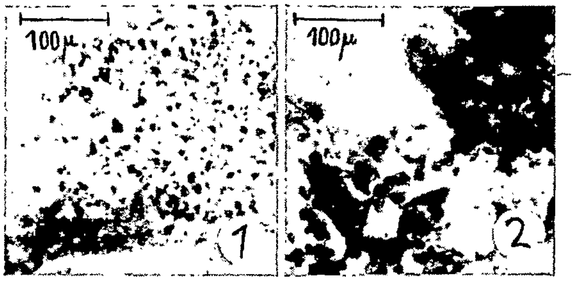
Histochemical Demonstration of Lipase and Alkaline Phosphatase Activity in the Fat Body of the Desert Locust

IN recent years several workers have studied by histochemical as well as quantitative methods the various metabolites and enzymes of the fat body of the locust. However, no information is available on lipase and alkaline phosphatase activity in this tissue. Here we report the results of a histochemical study undertaken to demonstrate lipase and alkaline phosphatase activity in the fat body of the desert locust (*Schistocerca gregaria*).



Fat body was removed from the abdominal region, after decapitation. The more readily dissected fat bodies thus taken consist mainly, if not solely, of true fat cells, the oenocytes being abundant towards the periphery, adjacent to the body wall[1]. Fresh frozen sections of this tissue was used throughout. For the demonstration of lipase, Gomori's 'Tween' method using 'Tween 80' as substrate was employed. 'Tween 80' is specifically acted upon by 'true lipase'[2]. Alkaline phosphatase was demonstrated employing the revised method of Gomori using sodium glycerophosphate as substrate. The procedures were the same as employed by us in our earlier work[3].

Figs. 1 and 2 present the photomicrographs of sections of the fat body of the locust treated respectively for lipase and alkaline phosphatase activity. Both the enzymes appear to be present in appreciable concentrations. In the case of the sections treated for alkaline phosphatase, there were present numerous round or ovoid bodies which stained intensely for the enzyme. These appeared to be the nuclei. The activity of these enzymes in the fat body is of special interest because this animal is known to utilize chiefly fat for muscular energy[4]. A high lipase activity in its flight muscles has also been recently demonstrated[5]. Similarly, high concentrations of lipase[6] and alkaline phosphatase[7] have been shown to be present in the fat-loaded fibres unlike the glycogen-loaded ones in the pigeon breast muscle, which is also known to utilize mainly fat for energy during sustained muscular activity[8]. Fat bodies of insects are often compared with mammalian liver since a number of metabolic reactions are known to be occurring in them. But more information is essential in order fully to justify such a comparison and the present study is an attempt in that direction.

Grateful thanks are due to Dr. K. B. Lal, plant protection advisor to the Government of India, for arranging the supply of the locusts used in this study.

BIOLOGY

A Rapid Method for examining Diapause Embryos of *Acheta commodus* W.

In the course of current work on the diapause of eggs of the common field cricket *A. commodus* it became necessary to determine the exact stage of embryonic development at which the arrest of development occurs.

Brookes[1] has described a method by which she traced the morphological development of non-diapause embryos of *Acheta*. The method involves fixing, staining and sometimes sectioning the eggs, and may take several weeks to complete.

In the present diapause studies, numerous observations are necessary to determine the onset and duration of diapause at different temperatures, so the long delay in the method used by Brookes would severely limit the scope of the work.

The desirability of using whole eggs rather than sections is evident. Slifer[2] found that by simply immersing eggs of *Melanoplus differentialis* in water the stages during katatrepsis can be observed under a dissecting microscope. However, diapause in *A. commodus* occurs during anatrepsis, the embryo is small and immersed in the yolk, and is not visible by this method.

The following treatment enables large numbers of eggs to be rapidly fixed and cleared in such a way that good optical differentiation of the embryo is provided without the use of stains (Fig. 1).

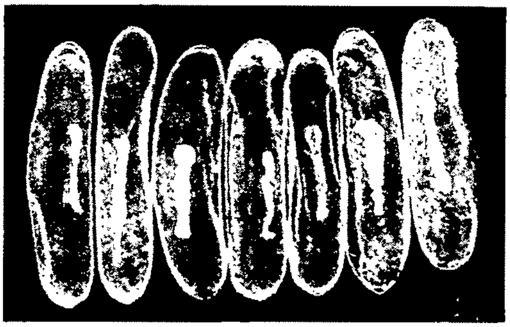

Fig. 1. Embryos of *A. commodus*, showing both diapause and early post-diapause stages of development. (× *c.* 12)

The eggs are placed in a watch box and soaked in water for about $\frac{1}{2}$ hr. The water is then drained off and replaced with the following mixture for 20–30 min. at 34° C.: glacial acetic, 2 parts; chloroform, 2 parts; absolute alcohol, 1 part. They are then transferred to a mixture of glycerol, 1 part, and alcohol (70 per cent), 1 part.

The first mixture will be recognized as having the same ingredients, in different proportions, as Carnoy's fixative. However, the fixative mixture is not effective. The time necessary in this solution varies with different batches of eggs according to their history, particularly the temperature at which they entered diapause. A preliminary trial for the timing is therefore desirable.

The time in the second solution is not critical. Clarity will be improved by standing at room temperature overnight and the improvement will continue for several days, but the stage of development can be identified within the first hour.

After the treatment the embryos are visible to the naked eye, but, for details of their morphology, the examination is made under a dissecting microscope. A black background and incident light are essential. Careful attention should be paid to the angle of incidence of the light.

I am indebted to Miss J. E. Kenyon for help in developing the method.

Influence of Larval Population Density on Fluctuation in Mosquito Numbers

Recent ecological studies on culicine mosquitoes in and around a village in south-western Nigeria[1] revealed that the numbers of *Aedes aegypti* fluctuated throughout the year in a manner which could not be correlated with the observed external environmental factors. During a preliminary survey it was established that this species was restricted to breeding within the village area in clay water-pots of the type used for collecting and storing water, but that it was absent from natural habitats in the surrounding rain forest. The fact that it showed a typically domestic breeding pattern facilitated a study of the population dynamics throughout the year, and the method used for obtaining an index of breeding intensity was as follows. A number of clay pots were placed in the village and sampled weekly, the pre-adults (larvæ and pupæ) being removed for counting while the pots were cleaned and refilled with fresh water. The number of pre-adults found weekly was taken as an index of the changes in density of the breeding population within the village.

To study this numerical fluctuation of *A. aegypti* the value N was used as a population index for the village, it being equal to $n/(e)(w)$, where n is the total number of pre-adults taken per month, e is the number of experimental pots sampled per month and w is the number of weekly samplings per month. During the first four months of the year, N increased from 24·3 to 135·0, this being followed by a sharp decline in May (52·6), a slight increase in June (71·2) and a continued decline until October (21·3). There was then a further build-up, reaching a peak in December (71·2). It will be seen (Fig. 1) that these fluctuations were not related to the observed environmental factors, either directly or with a suitable time-lag to allow for the climate to be influencing the egg-laying behaviour of the female. It was thought that these fluctuations may have been dependent on density, related to the numbers of larvæ and pupæ found in the pots. Each pot may be considered as an isolated environment containing a unispecific population subject to intraspecific competition, such that any increase in numbers beyond a certain point would result in an increased pre-adult mortality due primarily to starvation.

An examination of this postulate was carried out in the laboratory in the following manner. A series of cultures was maintained, each containing different numbers of larvæ but in otherwise standard conditions of food supply and water volume. To ensure constant food supply, a solution of larval food was made up having the following constituents: wholemeal flour (46 per cent), ground oats (40 per cent), fish meal (8 per cent), dried skimmed milk (3 per cent), cod-liver oil (1 per cent), dried yeast

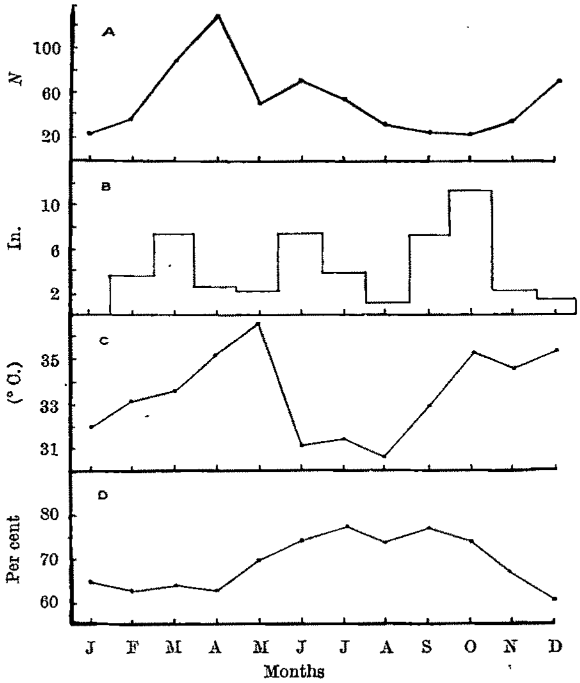

Fig. 1. *A*, the value of *N* for the village, 1956; *B*, the monthly rainfall; *C*, the monthly mean maximum temperature (° C.); *D*, the monthly mean minimum relative humidity (per cent). The monthly mean mimimum temperature varied in the range 18·1–20·5° and the monthly mean maximum relative humidity in the range 98·0–100 per cent

(1 per cent) and sodium chloride (1 per cent). 20 gm. of solid were added to 400 c.c. of water and heated to 100° C., the filtrate being used as the food solution. 40 c.c. of this were added to 1,000 c.c. of water and seven such cultures made up containing 10, 20, 30, 40, 50, 60, and 70 first instar larvæ respectively. A daily record was kept of development and mortality in each culture, the results for days 10 and 14 being given in Table 1.

In these laboratory experiments on the influence of population density on the survival and development of larvæ, each of the cultures described may be considered as a successive stage in the growth of a mosquito population.

In the field, the initial build-up may be accounted for by the early rains resulting in the hatching of the eggs which had remained viable over the dry season. At the time of the field study no rain fell between November 12, 1955, and February 9, 1956, but viability has been shown to persist in this strain for at least 24 weeks[2]. Thus the smallest culture may be taken to represent the commencement of the breeding season with the onset of the rains in February, each successive culture being a further stage in growth of population. It has been shown that in otherwise standard conditions, the greater the number of larvæ the longer the developmental period and higher the mortality. Thus it may be suggested at this stage that, in the field, as the population increas and relatively greater numbers of eggs were laid, t limits of the pre-adult environments were approache resulting in increased larval mortalities and a reduc egg-laying population. This decline was the followed by a recovery, it being suggested that there was adequate food material available for the smaller number of pre-adults. It may be concluded, therefore, on the present available evidence, that these fluctuations are essentially dependent upon density of population.

Table 1. Showing the Stages of Development on Days 10 and 14 of Cultures of *Aedes aegypti* Larvæ in Standard Conditions

Culture	No. of larvæ	Day 10	Day 14	Mortality (per cent)
1	10	8 IV, 2 III	10 *A*	0·0
2	20	20 III	20 *A*	0·0
3	30	30 III	15 IV	50·0
4	40	35 II	10 III	10·00
5	50	42 II	14 III	100·0
6	60	40 II	22 II	100·0
7	70	45 II	20 II	100·0

Note.—Roman numerals represent larval instars; *A* represents adults. After day 14 there was no further development in cultures 4–7.

Prolonged Survival of *Trichomonas vaginalis* at −79° C.

Successful cultures have recently been obtained from a stock strain of *T. vaginalis* which had been stored in a carbon dioxide cabinet for 26 months. The previous maximum survival reported was four months[1]. Since 1954, freezing in the presence of 5 per cent glycerol has been used for the maintenance of a strain of *T. vaginalis*. Stock cultures in the cabinet are replaced at approximately six-monthly intervals. Survival of cultures is shown on thawing by actively motile Protozoa and successful subcultures. The known maximum period of survival of such cultures has gradually been extended first to 8 months and then to 12 months.

Recently, four ampoules which had been frozon in September 1956 were examined. The first of these showed a few sluggishly motile Protozoa and was dispersed in 10 ml. of culture medium. There was no growth, probably because the sudden exposure to a glycerol-free medium disrupted the surviving cells. The suspensions from the next two ampoules which also showed very few active Protozoa, were each pipetted carefully to the bottom of separate tubes of medium so that the glycerol might diffuse out of the organisms as gradually as possible. Both these cultures grew, reaching maximum counts after 4 days incubation and thereafter subcultures grew normally.

The last ampoule was used in an attempt to obtain an accurate count of the proportion of surviving Protozoa. This failed, partly because the few survivors were too fragile to withstand the necessary manipulations and partly because many of the dead Protozoa were reduced to debris.

In all four samples active organisms were few and frail, and it may be that two years is close to the extreme period of survival for *T. vaginalis* under the conditions of storage, etc., used.

The growth and general appearance of the Protozoa after subculture were indistinguishable from a culture which had been stored for shorter periods, and both closely resembled the original culture prior to freezing. Antigens prepared from one of the recovered cultures and the one which had been more frequently passed were used for sensitizing sheep erythrocytes[2]. An anti-*Trichomonas vaginalis* rabbit serum, prepared in 1953, agglutinated red cells, sensitized with either of these antigens, to the same titre. The titre observed was somewhat less than that obtained with the same serum and culture five years previously, a difference which might be due to the age of the serum. No tests of pathogenicity were performed. As so few of the Protozoa survive, it may be that cultures derived from these form a selected group—this possibility cannot be ruled out.

The extreme period of survival recorded is not in itself important; but it does suggest that cultures may be kept for as long as a year with every confidence of survival.

A Toad (*Xenopus lævis*) without Hæmoglobin

de Graaf[1] has recently described a specimen of *Xenopus lævis* Daudin completely lacking hæmoglobin. Another specimen showing a similar condition was found in a practical class in this Department on September 20. The individual was a male measuring 6·5 cm. from the tip of the snout to the vent. Unfortunately it had been partly dissected under tap water and then left for some hours before my attention was directed to the specimen. It was one of a batch of toads delivered from the Trout Hatcheries near Kingwilliamstown in the Eastern Cape Province and had been in the laboratory for only five days before dissection.

As with de Graaf's specimen, the blood vessels were colourless or white except for the chromatophores in their walls; the heart was pale cream; the lungs and liver grey and, particularly striking, the kidneys cream. In contrast to the specimen found by de Graaf, the spleen appeared to be enlarged and was a light brown and not a slightly yellowish-white. The most remarkable feature, however, was that the gall bladder was rich in green bile pigment. This seems to suggest that extensive destruction of hæmoglobin had been occurring very recently.

de Graaf has shown that normal *Xenopus* are able to withstand functional elimination of at least 80 per cent of their hæmoglobin by carbon monoxide treatment. Although survival without hæmoglobin is clearly possible, he is careful to point out that this does not prove that an animal without hæmoglobin can be as active as a normal one. Nevertheless, in his discussion de Graaf appears to be assuming that his animal without hæmoglobin had been in that condition all its life, with the implication that growth to maturity in natural conditions is possible in the absence of hæmoglobin. The evidence that hæmoglobin destruction had only just been completed in the present specimen suggests a different interpretation—namely, that the totally anæmic condition is a pathological state which may arise after the adult has become mature. If this is correct then the existence of such individuals does not permit any conclusions to be drawn as to the importance of hæmoglobin for survival in natural conditions.

Inhibition of Influenza Virus Multiplication with a Glucose Antimetabolite (2-deoxy-D-glucose)

Optimal *in vitro* multiplication of influenza virus in the chorioallantoic membrane of the chick embryo is dependent upon the presence of glucose in the medium[1]. Evidence on the importance of endogenous glucose in *in vivo* synthesis of influenza virus is lacking. The relatively low toxicity in both experimental animals[2] and humans[3] of the potent glucose antimetabolite 2-deoxy-D-glucose suggested the feasibility of employing this compound in *in vivo* influenza virus infection. The present studies, undertaken in the intact chick embryo, demonstrate that the synthesis of influenza virus is markedly inhibited by 2-deoxy-D-glucose. Ancillary studies with *in vitro* systems show this inhibition to be reversible with glucose and therefore not related to permanent host cell damage.

The results of two representative experiments are shown in Fig. 1. In these experiments groups of six 10-day-old chick embryos were injected by the allantoic route with 12·5 or 25·0 mgm. of 2-deoxy-D-glucose or with water as a control. 18 hr. later, large inocula of influenza *B* (Lee) virus were introduced by the same route. These inocula were sufficiently large ($10^{7\cdot5}$ *EID*50, Exp. 559; $10^{8\cdot0}$ *EID*50, Exp. 560) to establish simultaneous infection of all susceptible cells to ensure a 'one-step' growth-curve. 8 and 24 hr. after the inoculation of virus, allantoic fluids from individual eggs were harvested and titrated with 0·5 per cent human '*O*' erythrocytes for the presence of viral hæmagglutinin. The geometric means of titres within groups were calculated and are plotted in Fig. 1. At 8 hr., viral concentrations in control eggs were close to maximal, while yields in eggs injected with 2-deoxy-D-glucose were

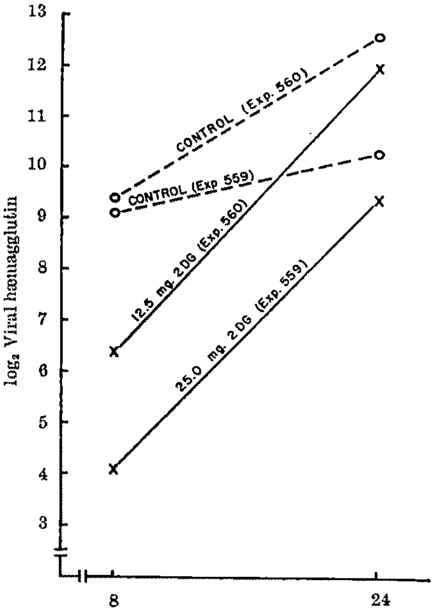

Fig. 1. Yields of influenza virus in allantoic fluids of chick embryos after prior injection of 2-deoxy-D-glucose (2DG). Geometric mean concentrations of virus derived from six individually titrated samples (allantoic fluids)/group. Chick embryos inoculated 18 hr. after injection of 2-deoxy-D-glucose with $10^{7\cdot5}$–10^8 50 per cent egg infectious doses (*EID*50) of influenza *B* (Lee) virus

3·0–5·0 $\log_2$ (8–32-fold) less. At 24 hr., however, hæmagglutinin concentration in eggs injected with 2-deoxy-D-glucose did not differ significantly ($>1·8$ $\log_2$) from control values. The apparent diminution in the inhibitory effect of 2-deoxy-D-glucose suggested: a declining efficacy of the metabolic block with time, or a slowed rate of viral synthesis with a delayed attainment of maximal titre as synthesis proceeded via less-efficient metabolic pathways not blocked with 2-deoxy-D-glucose. That the first interpretation is incorrect was demonstrated by an experiment in which virus was introduced 42 hr. after 25·0 mgm. of 2-deoxy-D-glucose at a time equivalent to the termination point of the experiments previously cited. The depression of yield of virus at 8 hr. was identical with that seen before. Hence it appears unlikely that interference with glucolysis had abated. This interpretation is supported by the failure of large amounts (50–250 mgm.) of glucose to prevent or reverse the effect of 2-deoxy-D-glucose in the intact chick embryo, although the effect induced *in vivo* was reversible *in vitro* by washing of chorio-allantoic membranes and the addition of supplementary glucose prior to virus infection. It is of interest that pyruvate, which may substitute for glucose in the *in vitro* synthesis of influenza virus[4], proved capable of inhibiting to a degree the restrictive effects on virus multiplication induced by 2-deoxy-D-glucose in the chick embryo. The utilization of pyruvate presumably is not blocked with 2-deoxy-D-glucose.

Other experiments have shown that synthesis of infective as well as hæmagglutinating virus is depressed with 2-deoxy-D-glucose, and that the ratio of hæmagglutinating to infective virus formed is equivalent to that of controls.

Preliminary experiments in mice have failed to demonstrate effects of 2-deoxy-D-glucose on either virus multiplication or the development of viral lesions. Further study of this relatively non-selective type of chemotherapy seems indicated, however, in view of the low toxicity of this antimetabolite. The possibility emerges that mere retardation of virus growth with preservation of host cell integrity may permit suppression of infection until natural host defences can be mobilized.

Whale Remains in Glacier Ice

THE preservation of Pleistocene or Recent land mammals in the Siberian permafrost has long been known, but the literature does not appear to include mention of marine mammals preserved in ice. Particular interest, therefore, is attached to the discovery in 1958 of part of a whale carcass entombed in the ice-cored moraine of Sveabreen, Ekmanfjord, in Vestspitsbergen. The north-eastern lateral morain of Sveabreen projects into the fjord about two mile beyond the ice-front, and the find was made b members of the Birmingham and Exeter Universitie Spitsbergen Expedition near the seaward tip.

The ice-core of the moraine rises to about 20 f above the high-water mark and the dirt cover i probably about 3 ft. thick. Near the top of th ice-core, and within the adjacent moraine, the bone and (now decomposing) flesh and skin of a whale wer found. Melting of the ice and the removal of morain seem to be uncovering more of the carcass each yea and, from what could be seen, much of the bod behind the shoulder region appears to remai Several of the posterior vertebræ are exposed on th upper surface of the moraine so that their dors surfaces have suffered some damage. The head an shoulders have been carried away during present-da erosion of the moraine, which consists here largely water-worn pebbles and small boulders and mu containing "raised beach" fossils typical of th "*Mytilus* horizon", that is, of the Sub-Recent perio Weathered-out vertebræ and ribs were found on th shore. The length of the existing part of the anima is about 30 ft. so that its length when complete mus have been about 60 ft.

The question of how and when the animal becam entombed is a difficult one. One would expect a dea whale to float and hence decompose during th summer months, even if it died in the winter. It i suggested, therefore, that this specimen was trappe beneath ice, possibly the floating ice-front of Sveabreen, and held there. Advance of the ice pushe the whale, together with sediment and the enclose shelly fauna, from the fjord floor to the position wher the moraine so formed is now situated. The lon axis of the whale is more or less parallel to the lengt of the moraine. It may be fortuitous that it lies a the top. As long as it remained in the permafros the animal would not decompose. It is surprisin that the body remained intact during the movement.

A regional recession of the ice in the Arctic ha been taking place during the past 200 years an certainly Sveabreen has retreated some two mile during the past 45 years. The whale must hav reached its present position at least before thi recession began and probably during the previou major advance of the ice, which occurred as a resu of a severe deterioration of the climate in Sub-Recen times. Ahlmann[1] suggests that this advance ma have occurred about 2,500 years ago. Since the and with the further recession of the glaciers, isostatic recovery has raised the Sub-Recent littor deposits on the Ekmanfjord coast 2–3 m. above sea level and with them the overlying ice-cored moraine Thus it may be surmised that the carcass of the whal reached its present site most probably more tha 200 years ago but not more than 2,500 years ago This time-interval is a large one; but radiocarbo dating would perhaps narrow the likely limit within which the whale died.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, January 26

Institute of Actuaries (in Staple Inn Hall, High Holborn, London, W.C.1), at 5 p.m.—Mr. Hilary L. Seal: "A Statistical Review of the Evidence for the Existence of Temporary Selection".

University of London Institute of Education (in the Assembly Hall, Malet Street, London, W.C.1), at 5.30 p.m.—Dr. C. A. Mace: "Field and Gestalt Theories".*

Institution of Electrical Engineers (at the Royal Festival Hall, London, S.E.1), at 6 p.m.—Dr. H. A. Thomas: "Automation" (Faraday Lecture).

Radar and Electronics Association (at the Royal Society of Arts, John Adam Street, London, W.C.2), at 7 p.m.—Mr. D. W. Fry: "The Pinch Approach to Thermonuclear Reactions".

Tuesday, January 27

University College (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. L. Brent: "A New King of Twin".*

Royal Society of Arts, Commonwealth Section (at John Adam Street, Adelphi, London, W.C.2), at 5.15 p.m.—Sir Vivian Fuchs: "The Commonwealth Trans-Antarctic Expedition" (Thomas Holland Memorial Lecture).

University of London (in the Anatomy Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. G. W. Beadle (California Institute of Technology): "Transmission Mechanisms"*. (First of two lectures on "Mendelian Inheritance". Further lecture on February 3.)

Society of Instrument Technology (at Manson House, Portland Place, London, W.1), at 6 p.m.—Symposium on "Flow Measurement".

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. P. Lloyd: "Some Aspects of the Engine Noise Problem".

Society for Visiting Scientists (at 5 Old Burlington Street, London, W.1), at 7.30 p.m.—Discussion Meeting on "New Light on Vision". Chairman: Prof. W. D. Wright. Speakers: Prof. R. W. Ditchburn, Prof. C. H. Graham and Dr. W. A. Rushton, F.R.S.

Wednesday, January 28

Geological Society of London (at Burlington House, Piccadilly. London, W.1), at 5 p.m.—Dr. R. J. Firman: "The Relationship between Joints, Faults and Mineral Veins in the Eskdale Granite (Cumberland) and the adjacent Borrowdale Volcanic Series"; Dr. W. I. Stanton: "The Lower Palæozoic Rocks of South West Murrisk, Ireland" (Paper read by Dr. G. Thomas).

Institution of Electrical Engineers, Supply Section (in conjunction with the British Nuclear Energy Conference, at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. A. E. Harwood, Mr. P. Scott and Mr. B. H. Stonehouse: "Design of Electro-Mechanical Auxiliaries Directly Associated with Power-Producing Reactors".

University College (in the Eugenics Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. A. Hald (University of Copenhagen): "A Survey of some Sampling Inspection Plans for Attributes".* (Further lecture on January 30.)

Challenger Society (at the Linnean Society, Burlington House, Piccadilly, London, W.1), at 5.45 p.m.—201st Scientific Meeting. Dr. Marston C. Sargent: "Growth and Photosynthesis in the Giant Kelp of the Pacific Coast".

Institute of Information Scientists (at the Berners Hotel, 10 Berners Street, London, W.1), at 6 p.m.—Discussions on (1) Abstracting, (2) Information Retrieval with respect to the results of the International Conference on Scientific Information, held at Washington, November 1958.

Institution of Mechanical Engineers, Education Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Teaching of the Theory of Structures and Strength of Materials".

British Institution of Radio Engineers, London Section (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Prof. D. B. Fry: "Theoretical Aspects of Mechanical Speech Recognition"; Mr. P. Denes: "The Design and Operation of the Mechanical Speech Recognizer at University College London".

Institute of Science Technology (in the Chemistry Lecture Theatre, University College, Gower Street, London, W.C.1), at 6.30 p.m.—Prof. Dame Kathleen Lonsdale, F.R.S.: "Peaceful Uses of Atomic Energy in the Next 50 Years".*

Society for Analytical Chemistry, Microchemistry Group (in the Restaurant Room of "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—Discussion on "The Determination of Small Quantities of Toxic Substances in the Atmosphere", opened by Dr. J. G. Gage.

Pharmaceutical Society of Great Britain (at 17 Bloomsbury Square, London, W.C.1), at 7.30 p.m.—Mr. K. R. Fell: "A Pharmacognosist in Nepal".

British Psychological Society, Medical Section (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 8.15 p.m.—Annual Meeting. 8.45 p.m.—Mr. A. Plaut: "Aspects of Consciousness" (Chairman's Address).

Thursday, January 29

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. A. Myers and Prof. R. D. Preston: "Fine Structure in the Red Algae", "The Structure of the Cell Wall of *Rhodymenia palmata*", "A General Survey of Cell Wall Structure in the Red Algae"; Mr. E. G. Gray: "Electron Microscopy of Collagen-like Connective Tissue Fibrils of an Insect".

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. C. T. Ingold, Mr. F. C. Webber and Dr. Irene M. Wilson: "Marine Fungi".

University College, Faculty of Laws (in the Eugenics Theatre. Gower Street, London, W.C.1), at 5 p.m.—Mr. D. W. M. Waters: "The Rating of Charitable and Similar Institutions".*

Institute of Biology, London Branch (at 41 Queen's Gate, London, S.W.7), at 7.30 p.m.—Dr. R. L. Knight, O.B.E.: "Fruit-breeding—a Survey of Recent Work"* (Annual Research Survey No. 4).

Thursday, January 29—Friday, January 30

Challenger Society (joint meeting with Representatives from the Marine Laboratories (Development Commissioners' Scheme), in the Lecture Theatre of the British Museum (Natural History), London, S.W.7), at 10 a.m. daily—Scientific Papers.

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2)—Convention on "Long-Distance Transmission by Wave-guide".

Friday, January 30

University College, Department of Pharmacology (in the Physiology Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. W. V. Macfarlane (University of Queensland): "Chemical Agents and the Slow Potentials of Heart and Muscle Cells".*

University of London (in the Eugenics Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. A. Hald (University of Copenhagen): "An Economical Sampling Inspection Plan based on *a priori* Distributions".*

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Dr. R. S. Silver: "The Energy Balance in Steam Power Plant Feed Systems".

Women's Engineering Society, London Branch (at Hope House, 45 Great Peter Street, Westminster, London, S.W.1), at 7 p.m.—Mrs. I. H. Hardwich: "Some Uses of Electron Beams in Metallurgy".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Mr. Yehudi Menuhin: "Art and Science as Related Concepts".

Saturday, January 31

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. Frank Greenaway: "Chemistry in Antiquity".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer or Lecturer in the Department of Pure Mathematics—The Registrar, The University, Liverpool (January 31).

Director (man or woman, of high ability, with considerable experience in chemical research and interest in its application in industry, able to lead and inspire a large research staff and organize and manage the work of the laboratory) of the National Chemical Laboratory, D.S.I.R., Teddington, Middlesex—The Civil Service Commission, 17 North Audley Street, London, W.1, quoting S.4923/59 (February 2).

Lecturer (registered medical practitioner) in Medicine—The Registrar, The University, Manchester 13 (February 2).

Lecturer in Mathematics; a Lecturer in Chemistry; and a Lecturer in Education—The Secretary, Homerton College, Cambridge (February 6).

Cytologist (honours graduate in botany or agricultural botany), to undertake general cytological work, but will have an opportunity to engage in original research—The Secretary, Scottish Plant Breeding Station, Pentlandfield, Roslin, Midlothian (February 7).

Lecturer (specially qualified in one or more scientific subjects) in the Institute of Education—The Registrar, The University, Liverpool (February 7).

Lecturer (Grade III or II) (with a good honours degree and some relevant research or teaching experience, preferably in the field of structures) in the Department of Civil Engineering—The Registrar, The University, Bristol 8 (February 16).

Senior Lecturer in the History and Philosophy of Science at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 16).

Lecturer (with special qualifications, and preferably some research experience in either glasshouse crops or fruit growing) in Horticulture—The Registrar (Room 22, O.R.B.), The University, Reading (February 18).

Director (with proven scientific ability in the field of nuclear sciences such as radiochemistry, nuclear physics, isotope techniques or theoretical physics and an interest and proven ability in using such fields of work to solve a wide range of scientific and applied problems) of the Institute of Nuclear Sciences, D.S.I.R., Wellington, New Zealand, to lead a research team of about forty scientists and carry out administrative duties therewith—The High Commissioner for New Zealand, 415 Strand, London, W.C.2, quoting Ref. No. *B*11/21/11 and mentioning *Nature* (February 20).

Lecturer or Assistant Lecturer (with a degree in physiology, biochemistry, pharmacology or experimental zoology and research experience in one of these branches) in the Department of Physiology and Biochemistry—The Secretary and Registrar, The University, Southampton (February 21).

READER IN BACTERIOLOGY at the Middlesex Hospital Medical School—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 23).

DEMONSTRATOR or SENIOR DEMONSTRATOR IN GEOGRAPHY, primarily to supervise class work in physical geography—The Registrar, University of Melbourne, Carlton, N.3, Victoria, Australia (February 27).

LECTURER IN AGRICULTURAL CHEMISTRY (BIOCHEMISTRY) at the Waite Agricultural Research Institute, University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 28).

LECTURER IN ORGANIC CHEMISTRY, and an ASSISTANT LECTURER IN ORGANIC CHEMISTRY—The Secretary, The Queen's University, Belfast (February 28).

LECTURER IN PHYSIOLOGY—Prof. A. A. Harper, Department of Physiology, Medical School, King's College, Newcastle-upon-Tyne 1 (February 28).

LECTURER (with a degree in science or veterinary science and undertaken postgraduate studies in parasitology) IN HELMINTHOLOGY OR VETERINARY PARASITOLOGY at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1, or the Registrar, University of Queensland, Brisbane, Australia (February 28).

SENIOR LECTURER or LECTURER (preferably with a degree or diploma in veterinary medicine and a specialized knowledge of comparative physiology) IN THE DEPARTMENT OF VETERINARY PHYSIOLOGY; and a LECTURER (veterinary surgeon, or with a degree in physiology) IN PHARMACOLOGY—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (February 28).

SENIOR LECTURER, and either a LECTURER or ASSISTANT LECTURER IN ZOOLOGY at Makerere College (The University College of East Africa)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (March 1).

RESEARCH ASSISTANT IN MATHEMATICAL STATISTICS in the Department of Applied Mathematics—The Registrar, The University, Liverpool (March 2).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS (2) IN CHEMISTRY, PHYSICS, ENGINEERING (including CHEMICAL ENGINEERING), METALLURGY, PHARMACOLOGY or related subjects—The Registrar, The University, Sheffield 10 (March 7).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN BIOCHEMISTRY, CHEMISTRY and PHYSICS—The Registrar, University College, Dublin (March 31).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN BIOCHEMISTRY, CHEMISTRY, CHEMOTHERAPY, ENGINEERING, METALLURGY, PHARMACOLOGY or PHYSICS—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 30).

TURNER AND NEWALL RESEARCH FELLOW IN ENGINEERING, INORGANIC CHEMISTRY or PHYSICS—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 30).

ASSISTANT EDITOR (full-time, with a university degree, preferably in the physical sciences, and interested in the general advancement of science—academic, industrial and social, no previous editorial experience necessary) of *Nature*—The Editor of *Nature*, Macmillan and Co., Ltd., St. Martin's Street, London, W.C.2.

HEAD (preferably aged 30–40, with a good degree and previous experience) OF THE CHEMISTRY DEPARTMENT—The Headmaster, Winchester College, Winchester.

LECTURER or SENIOR LECTURER (graduate in physics, teaching experience and preferably research and/or industrial experience) IN PHYSICS—The Principal, Kingston Technical College, Fassett Road, Kingston-upon-Thames.

NATIONAL RESEARCH COUNCIL and other POST-DOCTORAL FELLOWS IN THE DEPARTMENT OF PHYSICS—Prof. H. E. Duckworth, Chairman, Department of Physics, McMaster University, Hamilton, Ontario, Canada.

PHYSICAL CHEMIST (with an honours degree in chemistry and preferably a few years experience of applied research) IN THE BITUMINOUS SECTION of the National Institute for Road Research, South African Council for Scientific and Industrial Research, Pretoria, for work involving investigation of the different problems associated with the materials used for bituminous binders, and adhesion of tar, and bitumens to roadstone and the oxidation of tars and bitumens—The South African Scientific Liaison Officer, Africa House, Kingsway, London, W.C.2.

SCIENTIST (first- or second-class honours graduate in physics or electrical engineering), to be directly responsible to the Superintendent of Orfordness outstation for the general direction and day-to-day management of a team engaged on a programme of advanced electronic instrumentation development and associated complex field trials—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. No. 2131/34.

SENIOR TECHNICIAN IN THE RADIOTHERAPY DEPARTMENT—The Medical Superintendent, Western Infirmary, Glasgow, W.1.

POSITION AND FUNCTIONS OF THE RESEARCH ASSOCIATIONS

its first annual report last April, the Council for Scientific and Industrial Research said that it undertaking a comprehensive study of the way which the Department assists the promotion and lication of science in industry in Britain through work of grant-aided research associations. Apart n indicating that the Council was prepared to sider to what extent industries served by the arch associations could be expected to shoulder whole financial burden of an adequate research gramme either now or in the near future, the ort made no reference to immediate action. The ustrial Grants Committee of the Council, however, been surveying both the value of the work of the ciations and the methods used to assess and minister the Government grant ; and Government nt policy in relation to research associations is to reviewed during the present year in the light of survey.

Mr. John Wilson, lately director of research, tish Rayon Research Association, afterwards took nt-aided research associations as the subject of Hinchley Memorial Lecture to the British ociation of Chemists on October 29, but was ch more constructive than Dr. N. de Bruyne, in article in *The New Scientist* (3, 28 (78) ; 1958), to ose criticism he referred, as well as—though not te accurately—to that of Dr. H. Levinstein. Mr. lson's lecture was indeed concerned primarily to rify ideas as to the real functions of the grant-ed research association, and though he too recog-ed that the research association is at a disadvan-ge as compared with the research department of individual firm in selecting targets in techno-ical research, he fully recognized that there is a inite place for co-operative research. Quite apart m its function in providing for co-operation in the ack on common problems and perhaps particularly problems demanding very costly equipment or ources beyond those of individual firms, Mr. lson maintained that there is a definite place for research association in fundamental research, rticularly the systematic disciplined exploration of pecific field, which is irreconcilable with the com-te freedom of action of the universities.

The whole subject of co-operative industrial earch was carefully surveyed by Prof. R. S. wards in his book, "Co-operative Industrial search", published in 1950. Prof. Edwards did t indeed examine the essential functions of the earch associations, the broad fields of research ey should pursue or their relations with the iversities. His analysis was concerned with their nomic aspects and, as Dr. de Bruyne noted, advanced convincing arguments against the com-lsory levy ; though Dr. de Bruyne ignored the oad conclusion reached by Prof. Edwards both on his statistical evidence and on his inquiries into industrial opinion, that the research association is a sound industrial institution.

This is obviously the view of Mr. Wilson. He argues, indeed, that if research associations are used to attack problems common to groups of firms, the formation of a new research association will, in fact, lead to economy in the use of scientific man-power. Whether, however, it is cheaper to attack common problems on a co-operative basis or for individual firms to act independently and simultaneously depends on more than the selection of objectives which are worth while. It pre-supposes appropriate conditions of service, staff of similar high quality, and management capable of terminating an investigation at the right moment, as well as contacts between the research department and production which will ensure that the results are utilized as effectively when they come from the research association as they are within an individual firm.

There are questions of incentive and judgment involved here, and also of location, which can have a vital bearing on efficient communication, and these factors deserve more examination than they have yet received. Mr. Wilson and Dr. de Bruyne gave them no more attention than did Prof. Edwards ; but it is essential that they should be duly weighed in the re-assessment of the work of the research associations on which the Council of Scientific and Industrial Research is now engaged. Mr. Wilson makes an important point here in regard to staff, when he remarks, in urging that the research associations should give more attention to fundamental research, that the method of approach and type of man required for such work are quite different from those required in applied research. The difficulty can be over-stressed, for it is recognized in industry and has been overcome.

Much more important is the clear recognition of the relation between the research associations and the universities and also the research stations of the Department of Scientific and Industrial Research. This is probably essential in any event in order to check the danger of a research association becoming absorbed excessively in technical service, as distinct from research. A clear picture of the general structure of Britain's research effort and the respective functions of the universities, the independent research institutions, industry itself, the research associations and the Government research stations is necessary for the wise apportionment of effort and resources, and would contribute also to flexibility. It bears closely on the application of results, which is not simply a matter of the technique of communication but also, and sometimes mainly, of psychology.

Here, in touching on the communication of results, Mr. Wilson insists that the research associations must give some attention to information work; he suggests, nevertheless, that this function should be centralized in the Department's own Intelligence or Information Division. That is a debatable issue, too large to be discussed here; for it is, indeed, a facet of the library and information services of Britain as a whole, though it might be observed that Mr. Wilson's suggestion that such a step would release funds for research illustrates the way in which Government failure since the War to develop those services adequately has led to waste of effort and resources in research. Mr. Wilson is right, indeed, to point out how easy it is—and not only in the research associations—for resources to be diverted from the primary purpose and frittered away on secondary issues, even though these may be important. He mentions also education, and, valuable as has been the contribution of the research associations to technological education, this is not in itself a reason for their existence, and their research functions should be evaluated independently. Once the function of any particular research association has been clearly established and approved and the extent of the necessary resources determined, its ancillary contribution to technical education can be readily assessed. This should never be allowed to interfere with research itself, and it would be better to charge any direct loss involved to technical education as such, rather than allow it to appear in the research budget, unless it is impossible or impracticable to separate the two.

The main issue, however, is the proper function of the research association in Britain. Should it be, as Sir Lawrence Bragg suggested in 1942, an institution with a nucleus of permanent staff and with specialized and expensive equipment, but in the main with a constantly changing staff—a place to which men go for periods of intensive work, both from industry and the universities? Clearly, Mr. Wilson aimed at meeting the objection which Sir George Thomson advanced against Government research in his Fawley Foundation Lecture, in order to ensure the mobility which prevents fossilization. Mr. Wilson recognizes the value of the suggestion, but points out that success would depend on the existence of a virile organization in full operation, with a character, tradition and individuality of its own.

Mr. Wilson claims that the research associations possess the requisite resources for successful fundamental research, which requires the simultaneous impact of different disciplines, and can provide an atmosphere of freedom of discussion and publication which it is virtually impossible for the research department of an industrial firm to provide. He points out that, unlike the universities, they can accept directives from industry; but he suggests that their present low output of fundamental research could well be stimulated by administrative action in fixing the terms of future grants. He does not refer to the possibility that they might offer some contribution to the problem which the increasing cost of specialized equipment for research raises, and he does not mention the problem of continuity of finance.

These, however, are important factors on w among others, the decision as to the form in w research for any particular industry should prosecuted should depend. Conditions may widely from one industry to another, and alth there seems to be a sound *prima facie* case for tinuing in Britain the system of research associat in general, that is not to say that the existenc every research association is automatically justi Each needs to be examined in relation to its particular circumstances, and in relation to the o institutions which may serve that particular in try's need.

Finally, while the survey of the research ass tions and their work and functions on which Council of Industrial and Scientific Research is engaged is particularly welcome in view of the re announcement that the Department's resources to be substantially increased over the next five ye it is important that this re-assessment should made in relation to the functions of the Departme own research stations and of the universities th selves. Sound decisions cannot be made in isolati and while the expansion of the Departme resources makes it more desirable than ever that Department's organization and functions should periodically re-assessed as independently as poss in relation to present needs and conditions, i essential to realize that the Department is onl part of the nation's research effort. The repercuss on other sectors of the nation's effort need to considered also; nor should the large issue of administration and control of research be ignore

PAPERS AND CORRESPONDENC OF C. S. PEIRCE

Collected Papers of Charles Sanders Peirce

Edited by Arthur W. Burks. Vol. 7: Science Philosophy. Pp. xiv+415. Vol. 8: Reviews, Co spondence and Bibliography. Pp. xii+352. (C bridge, Mass.: Harvard University Press; Lond Oxford University Press, 1958.) Each 63*s*. net.

ON the east of the Atlantic, all too little is kn of the breadth and profundity of this Ameri philosopher's work. In the course of his life (18 1914), Peirce touched upon many problems wel advance of his time: to read his papers to-day i see what a considerable prophet he was. Ev have not hitherto been too kind to his memo six volumes of his writings appeared between 1 and 1935, after which, for a variety of reasons, noth more was done until 1954, when Harvard Univer initiated new progress, and these two volumes the result. They are most welcome.

The earlier work of Peirce consisted of studies deductive, inductive, and symbolic logic; now th are joined by contributions to science and philosop with some reviews and correspondence. The sali feature of this immense activity is the combinat of an enviable analytic power with sturdy pract experience. The latter came about because Pe spent some thirty years in the service of the Un tates Coast Survey, investigating astronomical and eodetic questions. In that sense he was a precursor of the distinguished school established in Britain by the late Sir Gerald Lenox-Conyngham at Cambridge. To read these papers, written in the early eighties, on the reasons for, and limitation of, pendulum experiments is to gain a substantial insight nto the physics of the Earth. Peirce must have possessed something of a flair for discerning the ssentials of his subject.

However, it is as a philosopher that Peirce will be emembered: his views on what to do and how to do it (or how not to do it) tend to be devastating when applied to research in general. He provides iscriminants for the worth-whileness of tackling any iven set of propositions experimentally. These criteria concern priorities, time, cost, and so on, and seem close to the considerations which any responsible director of research would apply to-day. In his time, naturally, the play was not for the high stakes f the mid-twentieth century, but the theory is all there, and of great interest. Another example of his apier-like mind is his approach to the old game of 'twenty questions'. On his showing, a score of interrogations is far too generous an allowance; something like half that number should reveal almost anything, if every shot carries the maximum possible epistemological weight. All this points inevitably towards the growth of a new science, that of cybernetics and information theory, utterly unknown during Peirce's life-time, but destined to become of major importance hereafter. If alive now, he would be a master of electronic computers. Another example of his power of foresight, as Prof. A. D. Ritchie has noticed, is his grasp of the influence of order of magnitude upon the aws applicable to single particles on one hand, and to assemblies on the other. Taken for granted o-day, Peirce perceived this more than sixty years ago.

The collection of reviews and correspondence strengthened by a detailed bibliography) portrays Peirce as a distinguished reviewer, kindly but ruthless in pressing an author's meaning to the limits of both philological and semantic significance. He seems to extract from a book considerably more than the writer probably intended to put into it. This applies more particularly to minor works, but when dealing with a major theme like Lobachevski's "Geometrische Untersuchungen", his comments are masterly.

It may be useful to indicate the plan and contents of the bibliography, more particularly since much of the material had its origin in rather unlikely places. The general scheme is: (1) Science of Discovery, (2) Science of Review, (3) Practical Science and Miscellaneous, (4) Book Reviews, (5) Life and Letters. This is, in fact, the author's own pattern of taxonomy, and depicts once again the unique quality of his mind. It should perhaps be added that a number of unpublished manuscripts still remain, which are of value for an assessment of his place in the development of philosophy in America. The general bibliography covers the period 1860–1911, with the addition of a few undated entries. Another section follows, containing items from *The Nation*, including Peirce's review of the two volumes of J. Willard Gibbs (1907). Lastly, comes a list of miscellaneous entries and indexes (cross-references, proper names and subjects).

If ever a work deserved the time-honoured title of the "Theory of Knowledge" these volumes certainly do. The editor and the Harvard University Press are to be congratulated upon their efforts.

F. I. G. RAWLINS

THE KILLING OF MICRO-ORGANISMS

Disinfection and Sterilization.

By G. Sykes. (Spon's General and Industrial Chemistry Series.) Pp. xviii+396+7 plates. (London: E. and F. N. Spon, Ltd., 1958.) 75*s.* net.

THIS book is a survey of the physical and chemical methods of killing micro-organisms. The scope is wide and the author, who has purposely avoided the subjects of chemotherapy and antibiotics, has condensed the material into 370 pages. Although this has prevented any detailed discussion it has permitted some cases of repetition in different sections of the book.

The subject-matter can be divided into two main sections, the physical and the chemical methods (sterilization and disinfection). Parts 1 and 5 of the book deal with the chemical methods and Part 2 with the physical ones. The disinfection and sterilization of air (Part 3), the disinfection of viruses (Part 4) and preservatives (Part 6) are treated separately.

Part 1 deals with the theory of disinfection and methods of testing. In the brief section on bacterial enzymes the difficulty of differentiating between disinfectant action and chemotherapeutic action has forced reference to some chemotherapeutic agents.

The treatment of the dynamics of disinfection is brief and no mention is made of the probit percentage survivor/time curves used by many modern workers, including Jordan and Jacobs, who are so often quoted in this section.

Details of many of the methods of testing are stated although little is given on the comparison between the methods, or with other methods of biological assay.

The chapters in Part 2 deal with sterilization by heat, radiations, filtration, gases and vapours, and the effects of cold, desiccation, and cellular disintegration. Each chapter is comple [illegible] in itself, but the reader will have difficulty in fin [illegible] which is the most efficient method for sterilizing [illegible] ecific material.

Part 3 is a concise an [illegible] l-balanced account of the disinfection and steriliza [illegible] of air.

Most of the short sectio [illegible] disinfection of viruses could be incorporated in [illegible] sections of the book since all the virus-inactiva [illegible] ents mentioned in this section have more deta [illegible] eatment in other sections.

In Part 5 the commonly used [illegible] ctants are discussed under the headings: phe [illegible] related compounds, dyes, quaternary amm [illegible] compounds, halogens, and heavy metals. The [illegible] are comprehensive but, although the coal [illegible] nfectants constitute the most widely used group [illegible] problems associated with their formulation receiv [illegible] little consideration. The testing of 'quats' wo [illegible] more appropriately discussed in Chapter 3.

It is essential that any book on disin [illegible] should discuss the problems of microbial spoil [illegible] Part 6 deals adequately with this, and quite [illegible] ly other causes of spoilage are not mentioned.

The book is well indexed and th [illegible] graphy is extensive, although the practice [illegible] ring to a 'private communication', which has [illegible] en made or is not going to be made freely av [illegible] ble, is very frustrating.

It will be a valuable reference volume in all microbiological libraries.

A. M. COOK

REFLEXIONS ON THE MOTILITY OF MUSCLE

The Motility of Muscle and Cells
By Prof. Hans H. Weber. Pp. vii+69. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1958.) 28*s*. net.

PROF. WEBER'S book might aptly have borne the sub-title '*multum in parvo*', for in 58 well-spaced pages of text he not only describes the biochemical basis of motility in striated and smooth muscle and in a number of unicellular organisms, but also puts forward a theory of the transformation of chemical energy into work during the contraction process. So far as the descriptive passages are concerned, there can be nothing but praise, particularly for the elegant techniques used in investigating the specialized movements of cells in mitosis, of fibroblasts and of *Vorticella*. Doubts quickly arise, however, when we consider the theoretical interpretation of the highly specialized contraction of striated muscle.

Prof. Weber sets out "towards the unknown region" from the postulate, well supported by innumerable experiments, that the energy for contraction is derived from the splitting of adenosine triphosphate by the actomyosin of the myofibrils in the presence, specifically, of magnesium ions, whereas no energy is required for relaxation, which is a passive process brought about by adenosine triphosphate, when its splitting is inhibited. To this he adds the further postulate that the physical changes of state take place according to the muscle model of Hanson and Huxley. This may be visualized, in the sense used by Prof. Weber, by considering the sarcomere at rest as a collapsible compartment, bounded by the *Z*-disks to each of which is attached a set of rigid pistons, the actin filaments, sliding freely within a centrally disposed cylinder, the *A*-band, made of parallel rigid filaments of myosin. During contraction, the pistons are envisaged as being pulled forcibly into the cylinder, rather in the manner of an iron bar into a solenoid. The problem is then to explain the nature of the attractive force in terms of these two premises. This Prof. Weber does by assuming the reaction occurs in steps, each of which consists of (*a*) a phosphorylation of a group on the actin piston, (*b*) the interaction of this group with a group on the myosin 'cylinder', resulting in dephosphorylation, and (*c*) further interactions between the dephosphorylated group and groups on the cylinder, each of which has a higher equilibrium constant than the one preceding it, or as Prof. Weber puts it, a lower standard energy in the temporary bonds formed. Attractive as this idea may be, it seems to be founded rather insecurely, because the results of Ulbrecht and Ulbrecht on which the very first interaction is based show that the postulated phosphorylation of protein by adenosine triphosphate occurs only with natural, and not with artificial, actomyosin, in spite of the fact that either sort of protein will form equally contractile threads. Apart from this objection, there is also the question of how sufficient of the energy derived from the primary phosphorylation is stored in the actin group to be available for the later interactions, without also postulating a complex series of configurational changes in this actin group, in other words, entropy changes, all of which must be reversed before the next step can take place.

When we pass from the steps to the integrat
movement of the whole sarcomere we encount
another difficulty which has apparently escaped th
notice of the adherents of the piston-and-cylind
model. That is, the question of how heat is giv
out during shortening. As is well known, Pro
A. V. Hill has been at great pains for many years
demonstrate once and for all that the total energy
contraction *in tres partes divisa est*, of which the fir
is the heat of activation, liberated explosively
soon as the stimulus arrives, and found to be consta
and independent of length or load; the second is th
heat of shortening, which is a linear function of th
degree of shortening and is also independent of loa
and the third is the work done. The latter two ma
up the so-called extra energy which can appear on
if the muscle is allowed to shorten and do wo
and which is entirely absent from the ideal isometr
twitch. Now, Prof. Weber's scheme does not ta
into account the first part of this energy release, th
heat of activation, presumably because it is difficu
to explain by simple thermochemical reasoning fro
this model or any other. It has been likened by so
workers to a charging-up process in contrast to shorte
ing, which is a discharge process; but if this were s
and no entropy changes were invoked, it woul
mean that more or less charged molecules would
left over at the end of a twitch, depending on wheth
the shortening were restricted or free. What woul
happen to the heat then ?

Secondly, reasoning from the model, Prof. Webe
concludes that it is unique in satisfactorily explaini
the origin of the heat of shortening; but this is onl
so if further restrictions are applied. For exampl
the scheme shows only one active group of acti
interacting at each step with four or more groups
myosin, although it is implicit that there are othe
behind it on the free part of the piston. If so, tw
courses are open: (1) interaction will occur wit
increasing frequency as the piston is pulled farthe
into the cylinder, that is, as more actin groups ar
opposed to more of the myosin steps, or (2) the acti
groups are discharged as they enter the cylinder an
afterwards remain inactive. If the first, then th
extra energy released in free shortening is a paraboli
function of the distance moved, that is:

$$-\text{Heat} = -K\,(n^2 + n)/2$$

where K is a constant and n is the number of step
This is clearly incompatible with Hill's equation an
must be rejected. On the other hand, if the secon
then only a restricted area at the end of the myosi
cylinders can contain active groups. Now this i
compatible with the linear heat relation, but it ru
counter to generally accepted views of the orientatio
of the *A*-band material and, for that matter, o
myosin itself. If we must reject this idea, then w
are left only with its opposite, that active groups ar
disposed throughout the length of the myosi
cylinder whereas those on the actin pistons ar
restricted to an area at their tips. This is a rath
more plausible concept, if no less revolutionary tha
the other, yet it still faces us with the problem o
how a long chain of homogeneous protein, perhap
extending for 10^4 angstroms, can be protected fro
interactions, except at its tip. Is it possible that thi
role is fulfilled by tropomyosin, a protein the functio
of which is as yet unknown ? Or must we abando
the piston and cylinder model in spite of its attractiveness in other ways ?

It is in raising these questions in such a precise and concise manner that the great merit of Prof. Weber's book lies, and while we may not agree with him over details, it is undeniable that he has successfully delimited the area where the answers will one day be found.

METEOROLOGICAL AND IONOSPHERIC STUDIES IN THE ARCTIC

Polar Atmosphere Symposium, Oslo, 2–8 July, 1956

Part 1: Meteorology Section. Edited by R. C. Sutcliffe. Pp. xi+341. 70*s*. net. Part 2: Ionospheric Section. Edited by K. Weekes. Pp. xiii+212. 60*s*. net. (London and New York: Pergamon Press, 1957 and 1958. AGARDograph No. 29. Published for and on behalf of the Advisory Group for Aeronautical Research and Development, North Atlantic Treaty Organization.)

DURING and since the Second World War, networks of meteorological observing stations making upper-air observations by radio-sonde have been established in the American Arctic by the United States and Canada, in Greenland by Denmark and the United States and in the Russian sector by the U.S.S.R. In addition, temporary aerological stations have operated on ice floes and observations by regular Arctic weather reconnaissance flights have been made by using 'drop-sondes' along their tracks. It appears, however, that at the time of the conference much of the Arctic aerological data not only remained unpublished but also some were unavailable. The majority of the twenty-four papers on meteorology are concerned with the analysis of the available upper-air data though, besides these synoptic and aerological studies, there are also accounts of the recent climatic changes in the Arctic, of radiation measurements, of visual range and 'whiteout' and of the distribution of ice in Arctic seas. The discussions that followed the papers are admirably reported and make interesting reading, often ranging into wider issues than those raised by the papers that initiated them. They include, for example, an exchange of views between Scherhag, Sutcliffe, Namias and Fjörtoft on the warming effect on the stratosphere which Scherhag some years ago attributed to the occurrence of a solar flare. The revelation that many local winds ascribed to steep slopes are often, in fact, unconnected with the slopes, led to a suggestion that certain classical text-book concepts require revision. A further assertion that the concepts of synoptic analysis should be included in this revision called forth an immediate and vigorous defence of frontal analysis by distinguished meteorologists.

About half the twenty-one papers presented to the Ionospheric Section deal with the methods, results and theory of ionospheric drift measurements. The discussion naturally centred on the interpretation of the results in different conditions as representing true winds or the effect of electric fields, and on the difficulty of determining the height to which the drift measurements refer. There follow papers on prediction techniques applicable to problems of polar communication, on absorption measurements and one on a theory of meteor echoes of long duration based on atmospheric turbulence. This volume concludes with a short report of a discussion of measurements of absorption associated with the solar event of February 23, 1956.

The planning of work in the Arctic during the International Geophysical Year must have been materially assisted by this meeting of meteorologists and ionospheric physicists at Oslo during the summer of 1956, though it is hinted in at least one of the papers that the concentration of activity on the Antarctic would inevitably limit the scope of the effort in the Arctic.

JAMES PATON

INTRODUCTORY ELECTRONIC THEORY

An Introduction to Electronic Theories or Organic Chemistry.

By G. I. Brown. Pp. vii+209. (London and New York: Longmans, Green and Co., Ltd., 1958.) 15*s*. net.

A PROBLEM confronting all writers of elementary text-books on the mechanism of organic reactions is the marriage of theoretical conclusions with suitable experimental evidence which is within the knowledge of the reader. Elementary text-books often have the tendency to particularize general reactions of classes of compounds in terms of the simplest members. These are seldom characteristic members of the class. The problem is a difficult one and the author has courageously, and probably rightly, avoided it by omitting the experimental material so far as possible.

This book is clearly and easily written and the argument simply stated. The usual topics are discussed, including electrophilic and nucleophilic substitution, the molecularity of reaction, hydrolysis, addition and elimination reactions, hydrogen-bonding and homolytic and heterolytic fission. The book has also a good historical introduction and very useful chapters on the nature of bonding. There is also a timely appearance of the high value of the latent heat of sublimation of carbon, evidence for which is now compelling.

As each topic is dealt with separately, the book will prove a ready source of information as well as being useful for reference. The text is clearly printed and attractively presented, the whole work being well indexed. The diagram, except for the point mentioned below, is well constructed and produced.

There are some matters with which I disagree. The discussion of the nitration of *p-ter*butyltoluene comes to an erroneous conclusion; recent evidence strongly favours a steric explanation of the experimental observations. The suggested mechanism for the Hofmann degradation (p. 193), moreover, would not meet with universal approval.

Finally, there are some trivial errors. The display of the electrons in the diagram (p. 34) suggests an interpenetration of the valency orbits of the oxygen atoms, and the failure to assign the $—NO_2$ and —COOH groups to particular carbon atoms on p. 196 is confusing at first sight. Surprisingly, collinear has been mis-spelt.

In spite of these criticisms, however, I consider the book to be well constructed and deserving of serious study. If it reaches the classes of readers, sixth-form students, first-year university students and older chemists who are interested, as the author wishes, it will do much to ensure a greater appreciation of this important subject.

R. I. REED

Feedback Theory and Its Applications

By P. H. Hammond. (Applied Physics Guides.) Pp. 348. (London: English Universities Press, Ltd., 1958.) 35*s.* net.

A GOOD understanding of feedback theory is essential for electrical engineers and workers in allied fields. The basic principles of linear servomechanism theory have appeared in many books. Most practical servo-systems involve non-linear elements and it is pleasing to see that this field of study is well covered in this book in easily understandable form. A particular feature to be commended is the frequent description of practical electronic circuits, including values of components and details of operating conditions.

An introductory chapter gives the necessary mathematics for much of the work to follow, including Laplace transforms, differential equations and the convolution integral. The following chapters deal with basic linear feedback theory, including Routh's stability criterion and the Nyquist rule. In the latter the critical point is taken as $+1$ rather than the more conventional -1.

The frequency response function is discussed in detail and Bode's relation between gain and phase characteristics is clearly explained. Feedback principles are illustrated in a number of electronic circuits, including cathode followers and virtual earth amplifiers. Methods of stabilizing amplifiers with several stages by the control of the frequency response are explained. Many applications of virtual earth amplifiers are given and a circuit using positive and negative feedback is described. A chapter is devoted to stabilization techniques applied to servomechanisms, and such topics as the use of derivative of error and integral control to reduce steady-state error are described.

The treatment so far given is inapplicable to many practical servo mechanisms because these use non-linear elements. The phase-plane technique is now explained and examples of its application are presented. The analysis of non-linear feedback systems presents considerable difficulties and one method is to employ frequency-response techniques and make use of describing functions. Further chapters describe on-off controlled servo mechanisms and simulation of servo mechanisms using analogue computers.

This book will be of great value to all workers requiring a thorough grasp of feedback principles.

R. L. Grimsdale

The Fabric of Farming

By Prof. A. N. Duckham. Pp. 224 + 8 plates. (London: Chatto and Windus, Ltd., 1958.) 15*s.* net.

PROF. A. N. DUCKHAM has written this book for first-year students, rural science teachers, and any others who are interested in the relation of agriculture to man. Such a public, while not likely to be looking for a profound treatise, will none the less expect the subject to be treated in a scientific manner. Prof. Duckham does this by considering the growth of agriculture from two points of view—the historical and the bio-geographical. He describes the development of farming from the days when man fed himself by taking the food he found in Nature, and hunting for animals and fish, to the complex undertaking that we know it to be to-day. He then discusses the influence of climate and of locality on type of farming, and the factors which result in extensive farming in some parts of the world, and intensive farming in others. Intensity and complexity generally go together and in most modern systems the skill of farming is largely measured by the success with which natural and man-made resources are integrated to produce the highest income in relation to their cost. "Weaving the many components of modern farming into a living, persistent, and profitable fabric calls for managerial ability of a high order on the part of the individual farmer and for a vast array of industrial, technical and social supplies and services, that is, for a high level and a wide range of inputs of non-farm origin." This way of looking at farming is born of a different 'habit of thinking' from some schools of thought. It is certainly different from the conception of agriculture as a nucleus of husbandry with the so-called ancillary subjects or sciences to hand, ready to assist the main subject when called upon to do so. Prof. Duckham insists that integration is a 'mode of thought' rather than a 'set of principles'; this, indeed, gives the clue to his approach to his subject.

"The Fabric of Farming" will not compete with "Fream" or "Watson and More" as the students' *vade mecum* in his contests with examiners, but it will give him more ideas in 200 pages than many books two or three times as big.

Harwood Long

Blood Groups in Man

By Dr. R. R. Race and Dr. Ruth Sanger. Third edition. Pp. xix+377. (Oxford: Blackwell Scientific Publications, 1958.) 42*s.*

THIS is now the third edition of this book, which has been deservedly popular. Since the last edition many new blood-group antibodies have been discovered which define new blood-group antigens but, on the whole, these have been found to be associated with the known blood-group systems; indeed, the authors state that it looks as if we are nearing the end of the blood-group systems which can be detected by the tests in use up to now, and express the hope that for the future of the science of human genetics, and for the delight of blood groupers, many more systems exist and that their recognition only awaits the devising of suitable tests. This pin-points the importance of the technical advances in this field over the past few years, which have made so much progress possible, and also indicates the predominant interest of these workers in human genetics, which is more evident in this edition than it was in previous ones.

Much more is now known about certain blood groups, and their complexity has so increased that the chapters dealing with them have had to be lengthened; for example, no one would have thought, some years ago, that the P blood-group system would have attained the interest which it now has. All the new information has been included without increasing the size of the book, so that some subjects receive less space; for example, three chapters on Rh in a previous edition now become one. Where old material has been omitted a summary and references are retained—a help to those who are beginning their studies of this subject.

The authors state they have not altered the notation or adopted Prof. Ford's suggested blood-group notation, and this is a wise course to adopt in the present state of affairs; indeed, any such alterations ought to be by international agreement.

This book has now become an established favourite and the new edition will be welcomed by all those interested in human blood groups.

F. Stratton

METABOLISM OF NORMAL TISSUES AND NEOPLASMS *IN VITRO*

By Prof. J. H. QUASTEL, F.R.S., and I. J. BICKIS
McGill-Montreal General Hospital Research Institute, 3619 University Street, Montreal

As is well known from the pioneer work of Warburg, characteristic features of tumour metabolism are the high rates of aerobic and anaerobic glycolysis coupled with low respiratory-rates. It is equally well known, however, that a number of normal mammalian tissues show relatively high rates of anaerobic glycolysis, but in these tissues glycolysis is largely abolished under aerobic conditions when oxidative processes are proceeding normally. In most tumours, the high rate of anaerobic glycolysis is reduced possibly to half its value when oxygen is present, but the glycolysis still proceeds at a relatively high rate.

The phenomena of a moderate respiration-rate and high sustained aerobic and anaerobic glycolysis are displayed not only by tumours. Warburg reported that the mammalian retina possesses a high aerobic glycolysis, although he considered that some sort of damage occurs in the preparation or examination of the tissue. A variety of normal tissues possesses characteristics ascribed to tumours. For example, a high aerobic glycolysis obtains in placenta, in kidney medulla and in jejunum mucosa and in the myeloid cells of rabbit bone marrow. It seems, as Greenstein[1] has pointed out, that a *specific* tumour metabolism does not exist, and that no clear-cut distinction can be drawn between normal and tumour tissues on the basis of metabolic criteria. Yet tumours tend to show a fairly uniform metabolism, their chemical activities, however different in origin these tumours may be, resembling each other much more than do those of the many varieties of normal tissues that give rise to tumours. Tumours tend to converge, biochemically speaking, to a uniform type of tissue. Warburg[2] considers that cancer cells originate from normal body cells in two phases, the first phase being an irreversible injuring of respiration and the second being a process whereby some of the injured cells "succeed in replacing the irretrievably lost respiration energy by fermentation energy. Because of the morphological inferiority of fermentation energy the highly differentiated body cells are converted by this into undifferentiated cells that grow wildly—the cancer cells". He points out that the irreversible damage to respiration, which is held to be the first phase of carcinogenesis, "need not be an actual decrease in the respiration quotient but merely an uncoupling of respiration, with undiminished overall oxygen consumption". Warburg lays emphasis not so much on the absolute magnitude of respiratory-rate of tumour cells, but on the relation that obtains between respiratory- and glycolytic-rates. Weinhouse[3] points out that cancer cells show no obvious impairment of respiratory ability, there being "no doubt of the ability of miscellaneous tumours to convert glucose (and fatty acids) to carbon dioxide at rates similar in magnitude to that of non-neoplastic tissues". Moreover, the effects of metabolic inhibitors such as fluoride ion or dinitrophenol are similar in neoplastic and normal tissues[4]. There is no indication from such evidence that oxidative phosphorylation occurs in tumour mitochondria in a manner different from that in the non-cancer material.

It seems to us that more light may be thrown on the general problem of the relation between the aerobic and anaerobic aspects of metabolism, and on the significance of these aspects of metabolism for growth in tumours and normal tissues, by a systematic investigation of the quantitative relations existing between respiration, glycolysis and the rates of biosynthetic processes in these tissues.

If tumours, in spite of their abilities to carry out a variety of oxidations similar to those occurring in normal tissues, cannot utilize aerobic energy as efficiently as normal tissues owing to an uncoupling phenomenon, the ability of tumours to carry out certain biosynthetic changes aerobically should be diminished compared with that of normal tissues. Even the demonstration that tumour mitochondria resemble normal tissue mitochondria in bringing about oxidative phosphorylations does not necessarily imply that in the tumour cell the adenosine triphosphate made available by the mitochondria is as available for cell syntheses as in the normal cell. Only experiments with intact cells will make this information available.

We have, therefore, carried out experiments with tumours and normal tissues in an attempt to discover whether respiratory energy in tumours is less effective than that of normal tissues for biosyntheses, and whether glycolytic energy is superior to that of respiratory energy for such processes in tumour cells.

For the purpose of this investigation, we have concentrated our attention on the quantitative aspects of the incorporation of glycine into proteins of tumour and normal tissues. We have compared the amounts of glycine incorporated under aerobic and anaerobic conditions with the energy released by respiration or by glycolysis in terms of adenosine triphosphate formed by these processes. We have, in fact, compared the 'efficiencies' of a variety of tissues for amino-acid incorporation in terms of available adenosine triphosphate.

Our choice of a system of amino-acid incorporation for the study of energy utilization by tissues under aerobic and anaerobic conditions has been determined by the relatively recent studies that have shown that such incorporation is greatly dependent on the presence of adenosine triphosphate, or on the release of that substance. This incorporation may consist of an exchange reaction or a protein synthesis[7], but presumably a process of peptide-like bond formation occurs which is a system requiring energy[8-12]. It is known[13] that slices of normal rat livers and of hepatomas incorporate ^{14}C-labelled alanine or glycine into the slice proteins, the rate of incorporation into the hepatoma proteins being greater than that into the normal liver proteins. Zamecnik and Keller[14] point out that incorporation of several ^{14}C-labelled amino-acids into proteins takes place anaerobically in a cell-free liver homogenate so long as adenosine triphosphate or a system generating this substance is present. No competition occurs between the various amino-acids tested. Rabinovitz *et al.*[15] have found that incorporation of several labelled amino-acids into proteins of Ehrlich ascites carcinoma cells is supported anaerobically under conditions of active glycolysis (see also LePage, ref. 26, and Nyhan and Busch, ref. 27). They[15] show that 2,4-dinitrophenol inhibits oxidation-linked incorporation at concentrations at which it stimulates oxygen uptake, but it is a feeble inhibitor of amino-acid incorporation linked with glycolysis. A cell-free system incorporating ^{14}C-amino-acids into proteins has been prepared from Ehrlich ascites carcinoma cells[16], the activation of the amino-acid carboxyl group being also dependent upon adenosine triphosphate[17]. Ziegler and Melchior[18] point out that the amino-acid incorporation system of liver is dependent on integrity of the cell and is very susceptible to lack of oxygen, facts that can be interpreted on the basis of a demand for adenosine triphosphate both for activation and incorporation of amino-acid. A need for glucose for optimal incorporation of amino-acid into a tumour (Gardner lymphosarcoma) was demonstrated by Kit and Greenberg[19], who also found that glycolytic and respiratory inhibitors inhibit the incorporation. The incorporation of labelled glycine and alanine into lymphosarcoma cells was not greater than in the normal spleen cell[19]. Uptake, as well as incorporation, of amino-acids is a process requiring energy. Negelein[20] has demonstrated that uptake of L-histidine into a malignant rat sarcoma takes place anaerobically so long as glucose is present and that glucose stimulates the aerobic uptake.

Attempts have been made by us to answer the following questions:

(1) Is the respiration of tumours 'impaired' in the sense that energy derived from it is less effective in securing amino-acid incorporation into proteins than in normal tissues?

(2) Is the energy utilized for amino-acid incorporation into proteins as effective anaerobically (in the presence of glucose) as that aerobically, either in normal tissues or in tumours?

(3) Do tumours differ from other highly proliferating tissues, including those of the embryo, in the efficiency with which oxidative or glycolytic energy is used for incorporation of amino-acid into protein?

In the following preliminary studies we have investigated the incorporation of glycine-1-^{14}C into the proteins of Ehrlich ascites carcinoma cells and into the proteins of sarcoma 37, Novikoff hepatoma, Walker 256 carcinosarcoma, and a melanoma in *DBA* mice, as well as into the proteins of embryos (chick and rat) and of normal mammalian tissues.

We have calculated the amounts of incorporation in terms of adenosine triphosphate made available by respiration or by glycolysis. It is known[21] that tumour mitochondria give a P/O ratio of approximately 3·0, resembling, in this respect, the mitochondria of normal tissues[22].

We have used for the description of our results a term, which we call, provisionally, the 'efficiency quotient', which is the ratio of amino-acid incorporated into the protein to the adenosine triphosphate theoretically made available by respiration or by glycolysis.

If the respiration is given by the term Q_{O_2} then, taking P/O = 3·0, the available adenosine triphosphate is given by the term $Q_{ATP} = 6Q_{O_2}$. If the amount of incorporation of amino-acid into tissue protein is given by the term A in counts per minute per milligram dry weight protein, then the efficiency quotient E is equal to $A/6Q_{O_2}$. (The efficiency quotient could be equally well expressed in terms of moles of amino-acid incorporated per mole adenosine triphosphate. A simple calculation, given the experimental conditions, will give this ratio. We prefer the ratio as described, however, for the time being, until it is certain that the label in the protein is due only to the amino-acid incorporated.)

Again, if anaerobic glycolysis is given by the term $Q_{CO_2}^{N_2}$, then adenosine triphosphate made available by this process will be identical with this term, as a molecule of lactic acid liberated by glycolysis is accompanied by the formation of a molecule of adenosine triphosphate. Therefore, the efficiency quotient, for anaerobic glycolysis, will be given by the term $A'/Q_{CO_2}^{N_2}$, where A' is the amount of incorporation (counts per minute per mgm. dry weight protein) under anaerobic conditions in presence of glucose.

If respiration is carried out in presence of glucose, the efficiency quotient will be given by the term $A''/\{6Q_{O_2} + Q_{CO_2}^{O_2}\}$, where $Q_{CO_2}^{O_2}$ is the measure of the aerobic glycolysis and where A'' is the amount of amino-acid incorporation (counts per minute per mgm. dry weight protein).

Experimental Methods

All studies were carried out *in vitro* either with slices of tumours that had been grown in mice or rats or in fertile hen's eggs (at the chorio-allantoic membranes), or with washed ascites cells obtained from Swiss white mice after intraperitoneal injection. Ascitic fluid was withdrawn with a hypodermic syringe after six days growth and the cells were separated by centrifuging. They were washed three or four times with 8–10 volumes of cold isotonic saline to remove blood elements and soluble ascitic constituents. Sarcoma 37 was grown in white Swiss mice (subcutaneously or as ascites intraperitoneally) or in chick embryos. Normal tissues came mainly from hooded male rats in the weight-range 200–300 gm. 'Regenerating' liver was produced in these rats by surgical removal of the left and middle lobes. Rat embryos came from pregnant hooded rats and chick embryos came from white Leghorn eggs.

Solid tumours or normal mammalian tissues were cut into slices as soon as possible after killing the animals (by decapitation). The organs or solid tumours were placed in ice-cold Ringer media (without glucose) and tissue slices cut with a Stadie-Riggs slicer. Retina was cut into squares of 0·5 cm.^{2} and incubated as such. Embryos were used whole, with as little damage as possible, after removal of amnion and allantoic membranes. (Under the conditions of our experiments, no visible damage—apart from some change in opacity—took place in the embryos during the incubation procedure.) For each experiment tissue slices from one organ or tumour were used, with the exception of thymus, when slices from the organs of four animals were pooled. Tumours were only chosen that were free from visible necrosis.

The conventional Warburg manometric apparatus was used for estimating respiratory and glycolytic rates for the incubations in which the incorporation of glycine-1-^{14}C into the tissue proteins was measured. The Ringer media used were those described by Umbreit *et al.*[23], the calcium content, however, being 1·5 m*M*. Glucose, when added, was 10 m*M*. Glycine-1-^{14}C was diluted with non-radioactive glycine, so that the final concentration used was 2m*M*. The glycine was placed in the side tube of the Warburg manometer vessel and only tipped into the vessel after appropriate gassing with oxygen, or with

93 per cent oxygen + 7 per cent carbon dioxide or with 93 per cent nitrogen + 7 per cent carbon dioxide and thermal equilibrium at 37°. The total volume of medium in each vessel was 3 ml. In aerobic experiments (with air or oxygen) the centre wells of the manometer vessels contained potash for absorption of carbon dioxide. To ensure complete anaerobiosis, when using nitrogen – carbon dioxide mixtures, sticks of yellow phosphorus were inserted in the centre wells of the manometer vessels.

In all experiments, the results of which are quoted below, the radioactivity of the glycine-1-^{14}C incubated with the tissues was 10^5 counts per min. per vessel, the total incubation period being 1 hr. With ascites cells the incubation period was shortened to 30 min. to prevent too large a fall in *p*H in glucose media.

The wet weights of tissues used in each vessel were quickly obtained with a torsion balance, avoiding all possible injuries especially with retinæ or embryos. Dry weights were established by drying corresponding amounts of tissues, prepared and handled in exactly the same way, at 110° C., to constant weight. The amounts of tissues per vessel were kept approximately the same (80–100 mgm. wet weight).

After incubation, the manometer vessels were placed in crushed ice, their contents (cell and medium) were homogenized in a 'Teflon' pestle homogenizer, precipitated with trichloracetic acid (final concentration 13 per cent) and further homogenized. The precipitates were extracted three times with 6 per cent trichloracetic acid (first extraction carried out for 15 min. at 90° C. to remove nucleic acids), once with ethanol, once with ethanol-ether (3 : 1) at 60° C. for 10 min., once with ether, and finally the residual proteins were suspended in chloroform-ether (4 : 1), plated on aluminium disks and counted. The counting was done with a thin mica end-window Geiger-Müller tube and an automatic scalar and timer. The counted data were corrected for background and self-absorption. The activities given are the actual counts and are expressed as counts per minute per milligram dry weight protein.

Crabtree Effect and Aerobic Glycolysis

The relation between the values for aerobic glycolysis and the diminution of respiratory-rate brought about by the presence of glucose (Crabtree effect) is seen in the results, obtained with tumours, given in Table 1. These results indicate that the ratio of the aerobic glycolysis-rate $QCO_2(O_2)$ to the difference between the respiratory-rates found in the absence QO_2 and in the presence $QO_2(G)$ of glucose is constant, approximately 6, with the tumours under investigation.

Such a relationship would be expected if the adenosine triphosphate produced in the tumour cell is approximately constant, whether glucose is present or not, under the experimental conditions. We should then expect that adenosine triphosphate lost by operation of the Crabtree effect is approximately balanced by that gained by aerobic glycolysis. The following relation should hold :

$$\{QO_2 - QO_2(G)\} \times 2\frac{P}{O} = Q\,CO_2(O_2)$$

Table 1. RELATION BETWEEN AEROBIC GLYCOLYSIS AND CHANGE OF RESPIRATORY-RATE DUE TO GLUCOSE ADDITION

Tumour	QO_2 no glucose added	QO_2 with glucose present $= QO_2(G)$	$QO_2 - QO_2(G)$	$QCO_2(O_2)$	$\frac{QCO_2(O_2)}{QO_2 - QO_2(G)}$
Ehrlich ascites (1)	14·0	8·0	6·0	33	5·5
(2)	12·3	7·1	5·2	30	5·7
(3)	12·1	8·1	4·0	29	7·2
(4)	11·3	6·9	4·4	26	5·9
(5)	11·8	6·3	5·5	26	4·7 Average value = 5·8
Sarcoma 37 (solid, grown in fertile eggs)	9·8	6·6	3·2	20	6·2
Novikoff hepatoma	9·7	7·0	2·7	16·2	6·0
Walker 256 carcinosarcoma	6·8	5·4	1·4	9·0	6·4

The results given in Table 1 indicate that this relationship holds if P/O = 3·0, which is the experimentally observed value obtained with tumour mitochondria. The value of P/O = 3·0, for the intact tumour cell, would indicate that respiration and phosphorylation are tightly coupled in the tumour cells investigated.

The facts obtained are consistent with the view that there is a competition for adenine nucleotides by the hexokinase system in the tumour cell and the respiratory system in the tumour mitochondria[29,30]. Weinhouse[31] has pointed out that tumour mitochondria may be highly permeable to the adenine dinucleotide, diphosphopyridine nucleotide.

Effect of Glucose on the Aerobic Efficiency of Ehrlich Ascites Carcinoma Cells

Typical results showing the aerobic efficiencies of Ehrlich ascites cells for incorporation of amino-acid in the absence and in the presence of glucose are given in Table 2. The results make clear the conclusion that the efficiency with which these tumour cells, under aerobic conditions, incorporate glycine into their proteins as a result of availability of adenosine triphosphate is the same in the absence of glucose as it is in the presence of glucose. It is evident that energy released by tumour respiration, even in the absence of added glucose, is available for amino-acid incorporation, and is quantitatively as effective as the respiratory energy of rat embryonic cells as shown by observations given in Table 3. Moreover, the presence of glucose makes little difference to the efficiency of amino-acid incorporation in spite of the fact that the rate of respiration is considerably

Table 2. EFFECTS OF GLUCOSE ON AEROBIC AND ANAEROBIC EFFICIENCIES OF EHRLICH ASCITES CARCINOMA CELLS FOR INCORPORATION OF GLYCINE-1-^{14}C INTO PROTEINS

	No glucose added	Glucose added 10 m*M*

reduced by the presence of glucose. (Calculation shows that only a very small fraction of the available adenosine triphosphate is used for incorporation of glycine, approximately one mole of glycine being incorporated for 500 moles adenosine triphosphate released.) The diminution of available adenosine triphosphate by the reduction of respiratory-rate is apparently almost exactly balanced by that released by aerobic glycolysis. This phenomenon applies to other experimental tumours that we have examined and would seem to indicate that the high rate of aerobic glycolysis characteristic of tumours is a means whereby the tumour cell may retain its content of available adenosine triphosphate undiminished in spite of the operation of the Crabtree effect.

It has been shown by Emmelot and van Vals[24] that the incorporation of DL-glutamate-1-^{14}C and DL-leucine-1-^{14}C into the proteins of mammary carcinoma ascites cells is essentially the same whether glucose is present or not, a fact in agreement with the results given in Table 2. On the other hand, Davis and Busch[25] point out that the specific activities of proteins of slices of Walker 256 carcinosarcoma, following aerobic incubation with L-aspartate, L-glutamate, or L-alanine, all uniformly labelled with carbon-14, are markedly enhanced by the presence of glucose. It is possible that this result is partly (if not wholly) due to the aerobic conversion of each of these amino-acids, which are uniformly labelled, in presence of glucose, to a mixture of radioactive amino-acids the incorporations of which are independent of each other[14]. Nyhan and Busch[26] have indicated that L-glutamate is metabolized by Walker 256 carcinosarcoma *in vivo*.

Effect of Glucose on the Anaerobic Efficiency of Ehrlich Ascites Carcinoma Cells

Glucose is essential for anaerobic incorporation of amino-acids into Ehrlich ascites carcinoma cells. Results given in Table 2 show that the efficiency of glycolytic energy for incorporation of glycine into the tumour proteins is a little higher than that of respiratory energy. Both quotients, however, for the tumours investigated are of the same order of magnitude, and a variety of experiments have shown that the aerobic and anaerobic efficiency quotients for incorporation of amino-acid into proteins of the tumours investigated are approximately equal.

The aerobic efficiency is calculated on the basis of P/O = 3·0 for tumour respiration. If the value of P/O is significantly less than this, the 'efficiency' of respiratory energy for incorporation of amino-acid would increase and exceed that of glycolytic energy. It is evident that the results do not support the hypothesis that there is any 'impairment' of tumour respiration in the sense that respiratory energy is uncoupled from phosphorylation and, therefore, from an accompanying biosynthetic process such as incorporation of amino-acid.

It would be expected that the efficiency of adenosine triphosphate for incorporation of amino-acid into the tumour proteins would be independent of its source of production, either respiration or glycolysis. The fact that experiments with intact tumour cells show that aerobic and anaerobic efficiency quotients are approximately equal is good support for the conclusion that adenosine triphosphate is the main energy factor in the process of incorporation of amino-acid into the proteins of intact cells.

Efficiencies of Aerobic and Anaerobic Incorporation of Glycine into Tissue Proteins by Tumours and by Normal Mammalian Cells and Embryos

Results of a survey of the relative rates of incorporation of glycine-1-^{14}C into the proteins of tissues under aerobic and anaerobic conditions, glucose being present under both conditions, are given in Table 3. They demonstrate the following facts:

(1) The highest efficiency ratios, both aerobic and anaerobic, occur with the most rapidly proliferating tissues, namely, tumours and embryos. Thymus and pancreas, among normal mammalian tissues, have the highest aerobic efficiencies—possibly this is connected with their high capabilities for synthesizing proteins.

(2) The ratio of anaerobic efficiency to aerobic efficiency approximates to unity with tumours, the anaerobic value being usually a little higher than the aerobic. With adult tissues, the aerobic efficiency term usually exceeds the anaerobic value; this occurs also with embryos.

(3) Adult normal tissues having high respiratory activities (for example, kidney cortex, brain cortex) may have low aerobic efficiencies for the incorporation of glycine into their proteins. Similarly, normal tissues having relatively high anaerobic glycolytic activities (for example, kidney medulla, retina) may have little or no anaerobic efficiencies for the incorporation of glycine into their proteins.

Table 4. RELATIVE EFFICIENCIES OF EHRLICH ASCITES CARCINOMA AND CHICK EMBRYO FOR INCORPORATION OF GLYCINE AND L-PHENYLALANINE INTO PROTEINS

		E_{O_2}(G)	E_{N_2}(G)
Glycine-1-^{14}C	Ehrlich ascites carcinoma	1·6	1·7
	Chick embryo	2·4	1·5
Phenylalanine-2-^{14}C	Ehrlich ascites carcinoma	1·3	1·2
	Chick embryo	1·5	0·9

It should be pointed out that the aerobic efficiency quotients for incorporation of amino-acid into the proteins of adult tissues and embryos will need a small correction for the amount of radioactive protein produced from the radioactive carbon dioxide formed by oxidation of the amino-acid. This is largest with kidney cortex, but is negligible with Ehrlich ascites carcinoma cells and sarcoma 37, or thymus, which bring about very little oxidation of glycine to carbon dioxide. Chick embryo, rat brain cortex and rat liver have about one-sixth of the oxidizing power of rat kidney cortex on glycine for equivalent weights of tissue.

The results given in Table 3 make clear the fact that in the development of embryo into adult organs a marked drop takes place in the ability of the tissue to incorporate glycine into its proteins, although aerobically, and anaerobically with certain tissues (kidney medulla, brain cortex, retina), energy is apparently available in amounts comparable with those in the embryo. Further investigations are needed to establish the reasons for the diminished efficiency of adult tissue for incorporation of amino-acid into their proteins ; but one possible cause may be the development in the adult tissues of new enzyme systems dependent upon adenosine triphosphate, which are needed for the special functions of these tissues. Less adenosine triphosphate, therefore, is available for their amino-acid incorporating systems. The relative lack of the ability to incorporate amino-acid observed in adult tissues such as kidney or brain cortex, under anaerobic conditions in presence of glucose, points to the fact that in such tissues cytoplasmic, or extra-mitochondrial, adenosine triphosphate (made available by anaerobic glycolysis) cannot be used for incorporation of amino-acid. This stands in contrast to the effects of embryonic (or tumour) glycolysis. Further investigations, based on these conclusions, may help to throw light on the nature of the specific biochemical changes that arise with differentiation and growth of the embryo into the adult stage.

Observations recorded in Table 4 show that the conclusions concerning the incorporation of glycine into the proteins of Ehrlich ascites carcinoma cells and chick embryo apply also to L-phenylalanine, which was used under exactly the same experimental conditions as glycine. Investigations with other amino-acids are proceeding.

Tumour and Embryo

Tumours and embryos, which resemble each other in having relatively high efficiencies for the aerobic and anaerobic incorporation of amino-acid, show, so far as their metabolism is concerned, a number of significant differences. For example :

(1) The presence of glucose, which depresses respiratory activity of tumours, has but little effect on that of rat or chick embryo.

(2) The presence of malonate greatly depresses both the rate of respiration and the rate of incorporation of amino-acid into proteins of Ehrlich ascites carcinoma cells and of chick embryo in the absence of glucose. These results, which are shown in Table 5, are consistent with the fact that the citric-acid cycle operates in these tissues[31]. When glucose is added, however, malonate exercises relatively little effect on the rate of respiration of the tumour, or on the rate of incorporation of glycine, in contrast to its large effect on embryo metabolism in the presence of the sugar. It appears, therefore, that in the presence of the respiratory poison, which blocks incorporation of amino-acid into tumour protein, glucose reverses the effect—a phenomenon not seen with embryo. In this respect embryo resembles adult tissue more than it resembles tumour. Nyhan and Busch[27] have shown that malonate suppresses the specific activity of proteins of Walker 256 carcinosarcoma exposed aerobically to labelled glutamate, and that the addition of glucose alleviates this suppression.

The reversing effect of glucose on the depressing effect of metabolic inhibitors on the amino-acid incorporation of tumours is also seen in its action on Ehrlich ascites carcinoma cells in presence of bilirubin or 2 : 4 dinitrophenol. Representative results obtained with ascites cells, given in Table 6, indicate that bilirubin can act as an uncoupler of phosphorylation from oxidations, a conclusion already reached by Zetterström and Ernster[32] in their studies of the effects of bilirubin on liver mitochondria. The substance, at low concentrations, suppresses incorporation of glycine into the tumour proteins, an effect partially reversed by the addition of glucose. It abolishes the Crabtree effect, and resembles in these respects the action of 2 : 4-dinitrophenol (Table 6). It might be noted in this connexion that sarcomycin, an inhibitor of growth of Ehrlich ascites carcinoma, inhibits glycine incorporation into ascites proteins[33]. The inhibition is diminished by the presence of glucose, but not as much as when bilirubin or dinitrophenol is the inhibiting agent.

Table 5. EFFECTS OF SODIUM MALONATE ON METABOLISM OF EHRLICH ASCITES CARCINOMA AND OF CHICK EMBRYO (5 DAYS OLD)

	Q_{O_2}		Glycine-1-^{14}C incorporation into proteins (c./min./mgm.)	
	Ascites	Embryo	Ascites	Embryo
No glucose present				
Without malonate	10·9	8·0	144	159
With malonate 20 m*M*	4·8	5·6	12	69
With glucose present				
Without malonate	5·3	7·8	138	172
With malonate 20 m*M*	4·3	4·8	119	60

Table 6. EFFECTS OF BILIRUBIN AND DINITROPHENOL ON METABOLISM OF EHRLICH ASCITES CARCINOMA

	Q_{O_2}	Glycine-1-^{14}C incorporated in proteins (c./min./mgm.)
No glucose present		
Control	13·0	83
With bilirubin		
0·16 m*M*	8·8	13
0·32 m*M*	1·3	4
With 2 : 4-dinitrophenol		
0·1 m*M*	15·5	36
Glucose (10 m*M*) present		
Control	6·5	110
With bilirubin		
0·16 m*M*	10·3	51
0·32 m*M*	10·8	52
With 2 : 4-dinitrophenol	15·3	87

The fact that the addition of glucose may restore to the tumour, in the presence of inhibitors of oxidative phosphorylation, its ability to incorporate amino-acids in its proteins, emphasizes the biological importance of this sugar in enabling the tumour cell to withstand the toxic effects of certain metabolic poisons.

Summary

(1) The ratio of rate of aerobic glycolysis ($Q_{\rm CO_2}({\rm O_2})$) to the difference between the respiratory-rates found in the absence ($Q_{\rm O_2}$) and in the presence ($Q_{\rm O_2}({\rm G})$) of glucose is constant, approximately 6, with the experimental tumours investigated (Ehrlich ascites carcinoma cells, sarcoma 37, Novikoff hepatoma and a melanoma). This relationship is expected if the adenosine triphosphate produced in the tumour cell is approximately constant, whether glucose is present or not, the adenosine triphosphate lost by the Crabtree effect being balanced by that gained by aerobic glycolysis. The facts indicate that the following relation holds :

$$\{Q_{\rm O_2} - Q_{\rm O_2}({\rm G})\} \times 2\frac{\rm P}{\rm O} = Q_{\rm CO_2}({\rm O_2})$$

where P/O = 3, and that, therefore, respiration and phosphorylation in the intact tumour cell are tightly coupled.

(2) The efficiency with which the tumour cells under investigation incorporate glycine, under aerobic conditions, into their proteins as a result of availability of adenosine triphosphate is the same in the absence of glucose as it is in the presence of glucose. The efficiency term is defined by the ratio $A/Q_{\rm ATP}$, where A is the radioactive amino-acid incorporated into the tumour protein (given in counts per minute per milligram dry-weight protein) and $Q_{\rm ATP}$ is the available adenosine triphosphate calculated as equal to $6Q_{\rm O_2}$ under aerobic conditions in the absence of glucose or to $6Q_{\rm O_2} + Q_{\rm CO_2}({\rm O_2})$ in the presence of glucose, or to $Q_{\rm CO_2}({\rm N_2})$ anaerobically in the presence of glucose. The energy released by tumour respiration, in the absence of glucose, calculated on the basis of P/O = 3 for the tumour cell, is quantitatively as effective for amino-acid incorporation into tissue proteins as the respiratory energy of rat embryo.

(3) The efficiency of glycolytic energy for incorporation of amino-acid into tumour proteins is approximately equal to, though usually a little higher than, that of respiratory energy.

(4) A survey of the relative rates of incorporation of glycine-1-^{14}C into the proteins of a variety of tissues under aerobic and anaerobic conditions, glucose being present, shows : (*a*) The highest efficiency ratios, both aerobic and anaerobic, occur with the most rapidly proliferating tissues, namely, tumours and embryos. Thymus and pancreas, among normal mammalian tissues, have the highest aerobic efficiencies. (*b*) The ratio of anaerobic efficiency to aerobic efficiency approximates to unity with tumours, the anaerobic value being usually a little higher than the aerobic. With adult rat tissues, and with chick and rat embryos, the aerobic efficiency term usually exceeds the anaerobic value. (*c*) A number of normal tissues (for example, kidney medulla, retina), having relatively high anaerobic glycolytic rates, have little or no anaerobic efficiencies for the incorporation of glycine into their proteins. It would seem that extra mitochondrial, or cytoplasmic, adenosine triphosphate (made available by glycolysis) cannot be used in these tissues for amino-acid incorporation. This is to be contrasted with the efficiency of embryonic energy made available by anaerobic glycolysis. Many adult mammalian tissues show relatively low aerobic efficiency terms for amino-acid incorporation, as compared with those of tumour or embryo.

(5) Essentially similar results are obtained with tumour and embryo using phenylalanine-2-^{14}C instead of glycine-1-^{14}C.

(6) Tumours and embryos, which resemble each other in their high aerobic and anaerobic efficiency terms for amino-acid incorporation into their proteins, differ in their relative responses to the effects of malonate in the absence and presence of glucose. Although malonate greatly inhibits both respiration and incorporation of amino-acid into proteins of Ehrlich ascites cells and of chick embryos, the addition of glucose almost eliminates the malonate inhibition with the tumour cells, but has little or no effect on the malonate inhibition with chick embryo.

(7) Bilirubin, at low concentrations, suppresses incorporation of glycine into Ehrlich ascites cells. It acts as an uncoupling agent, and, like dinitrophenol, abolishes the Crabtree effect. Its inhibitory effect on amino-acid incorporation is partially reversed by glucose, which may play an important part in enabling a tumour cell to withstand the toxic effects of certain metabolic poisons.

THE FISH CULTURE RESEARCH STATION, MALACCA

By Dr. C. F. HICKLING, C.M.G.
Acting Director

FISH culture has the same object as agriculture and stock breeding, namely, to increase by all possible means the production of food far above the level which would be produced naturally. Like agriculture, fish culture includes the elimination of unwanted plants and animals, their replacement by desirable species, the improvement of these species by cross-breeding and selection, and the improvement of the substratum by the use of fertilizers.

The remarkable rate of increase of human populations is bringing increasing pressure on food production. In Malaya, for example, the population will, on present trends, double every twenty years. It is widely realized that every possible piece of suitable land must be brought into production, and great efforts are being made to do so. No less must every suitable piece of water produce the maximum weight of fish.

But whereas fundamental research in tropical agriculture does not lack research stations of the first magnitude, there has so far been lacking a research station, on the scale of a major agricultural station, for the fundamental study of fish culture. The Fish Culture Research Station at Batu Berendam, Malacca, was designed to fulfil this need. Its function may be briefly described as to give a new look to an ancient and stereotyped traditional technique.

The Station was built at a cost of some £235,000 to Colonial Development and Welfare Funds, and was officially opened on August 21, 1957, ten days before Malaya attained independence. The Station is intended to serve, in the first instance, all tropical Commonwealth territories; and so the problems it will tackle will be such as are common to all, or most of, these territories. It is intended to accept contributions from all such territories as are willing to support this work.

Batu Berendam is nearly five miles north-west of Malacca, on first-class tarmac roads; and the Station has municipal piped water and electricity. Besides the laboratory building, there are six houses for senior staff adjacent, and fourteen quarters for junior staff. The pond area is only some 400 yd. from the laboratory.

The Station is at approximately sea-level; there is no seasonal variation in either temperature or rainfall. Rainfall averages about 100 in. a year; air temperature varies but little from a diurnal range of 76–86° F.

The laboratory (Fig. 1) is a one-story building of modern design, with six working rooms in addition to offices, workshops and stores. There is research accommodation for eight scientists; as the establishment of the Station is for a director and five scientific officers, there is accommodation for visiting workers, who will be very welcome. The laboratory has been designed for extension as required.

Novel features of the laboratory are, first, an underground rain-water tank, from which rain-water collected from the roof is automatically pumped to a cistern at the top of the tower seen in Fig. 1, to descend by gravity through polyethylene piping to thirty-six concrete tanks, in which fish can be held for quarantine or examination, and in which they can be bred. Secondly, eight similar concrete tanks are in a blacked-out compartment with powerful 'daylight' lighting. An automatic time-switch enables fish or plants in this compartment to be subjected to whatever number of hours of 'daylight' an experiment requires. Interesting results might come from subjecting tropical fish, which know no seasonal variation in their length of day, to temperate lighting conditions.

The estate in which the fish-ponds are constructed is 170 acres of former swamp land; of these, 82 acres are actual water surface. There are 164 ponds, of a size ranging from breeding ponds of 1/100 acre, to ponds of 4½ acres. A unique feature of the Station is that, within each group, the ponds are identical in shape, area and depth. Fig. 2 shows some of the ponds.

The pond site is mainly composed of a heavy lateritic clay. This is an infertile acid soil with impeded drainage, which supports crop plants with difficulty, even after the addition of fertilizers. That part of the estate which has not been used for the construction of ponds is still largely swamp land and supports a stand of 'gelam' trees. These trees are known to grow well on land which proves sterile and often toxic when afterwards prepared for agricultural use. The harmful nature of such soils may be caused by a high concentration of soluble sulphates and aluminium salts which have been found to be present[1]. Seepage water from swamp land adjacent to the fish-ponds was analysed, and contained more than 0·1 per cent of sulphate and more than 6 p.p.m. of aluminium. This affects the pond water-supply, which is taken from the Malacca River (pH 6·0, sulphate negligible). After flowing through the canal, water taken at the pump house, which supplies the ponds, has a pH of 3·5 and contains more than 60 p.p.m. of sulphate.

Similar toxic effects, resulting from the drainage of swamp land, have been frequently reported (for example, in Uganda[2]). In spite of considerable agricultural research, the problem of using such land profitably remains largely unsolved. By using such land for fish culture, therefore, the Fish Culture Research Station at Malacca is doing pioneer work. Already it has been found that heavy crops of fish, including the Chinese grass carp, can be carried, apparently in perfect health and with rapid growth, in ponds constructed in 'gelam' soil. The effect of lime dosages will be given below.

The natural production of wild fish in such poor conditions is very low. Nine of the ponds belonging to the Station, which had had standing water in them for at least two years and still had the original

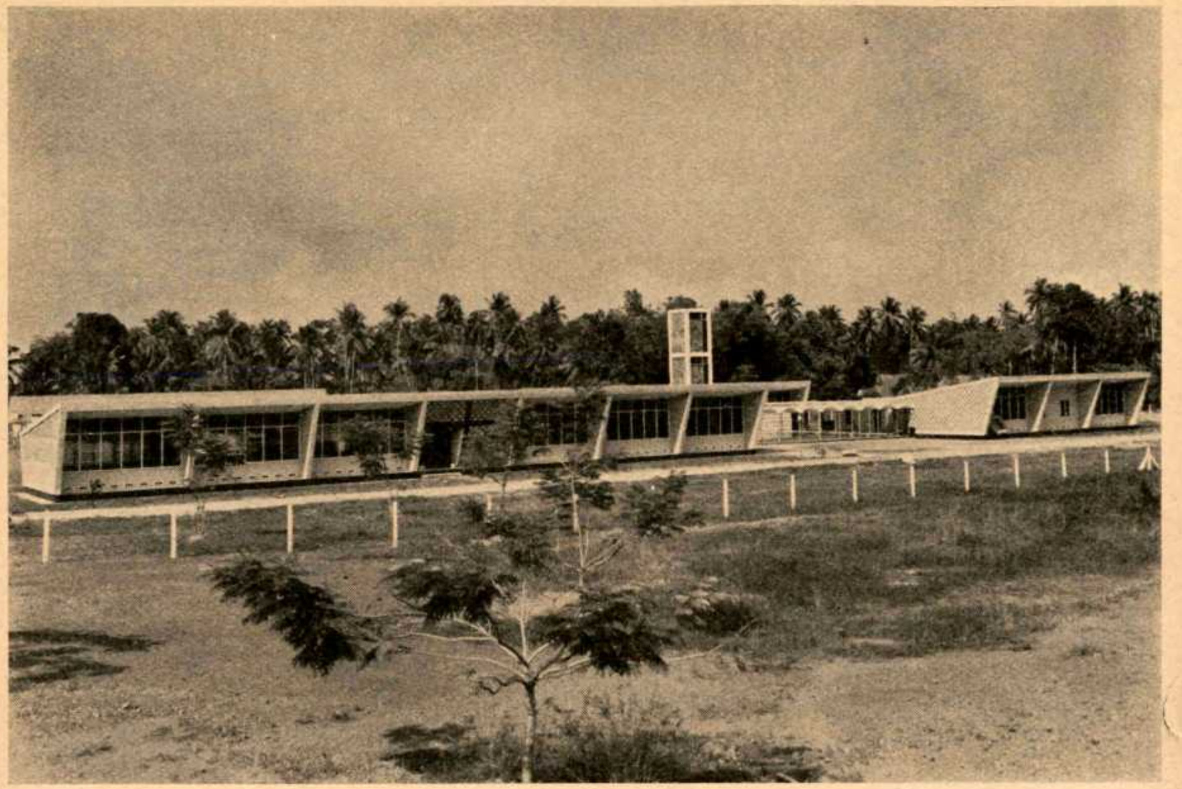

Fig. 1. The Fish Culture Research Station, Malacca

swamp-fish fauna, were cleared by the use of a suitable fish toxin, and the total fish population weighed. The average standing crop was 18 lb. per acre, comparable with the annual production of the fresh-waters of England and Wales, of Lake Tiberias in Palestine, and of Lake Mendota in Wisconsin[3].

By clearing away swamp vegetation, liming to neutrality, and stocking with desirable species, already yields at a rate of more than 300 lb. per acre per annum have been obtained, without the use of fertilizers, in these ponds.

Naturally, the work of the first year has been chiefly concerned with clearing the swamp vegetation from the ponds, and breeding stocks of fish to put in them. Nevertheless, a full-scale experiment has been carried out, in the thirty-six 1-acre ponds, on the effect of six levels of lime dosage each replicated six times, from zero to 2 tons per acre. In Fig. 3 is shown the effect on the *p*H of these successive doses. Each point is the mean for six ponds. It will be seen that the untreated controls had a *p*H of 5, and that the *p*H rapidly increased with increasing lime dosage until, after about 15 cwt. limestone per acre, the *p*H levelled out at about neutrality.

This quantity, namely, 15 cwt. limestone per acre, appears to be much less than that quoted by the text-books. Most authors follow Schäperclaus, who himself copied agricultural tables by Trenel. From Schäperclaus's table, heavy loams or clays, such as exist at the Station, of a *p*H of 4·5–5, would need 25 cwt. lime per acre, or say 50 cwt. chalk. The table published by Macan, Mortimer and Worthington[5] would prescribe 18–36 cwt. limestone per acre. However, these experiments at Malacca are the first, so far as I know, to be done on the large scale in conditions of very acid soil and water.

This work is continuing with an investigation of the effect on fish production of graduated doses of phosphate and potash, with and without limestone. The final object of this line of work is to increase the fish crop with the least expense, by using the best ascertained fertilizer mixture.

The changes in vegetation consequent on the clearing of the swamp vegetation, flooding with water, and the application of lime in various doses, have provided an interesting study.

From typical swamp consisting mainly of sedges, flooding alone tends to eliminate only short plants such as *Eriocaulon* and *Xyris*. The addition of lime, as well, suppresses the growth of *Rhynchospora aurea*, *Scleria poaeformis* and *Philydrum lanuginosum*, leaving *Fimbristylis acuminata* and *Isachne globosa* comparatively unaffected. These latter disappear only with regular cutting. As a result of liming, the typical lime-lover *Chara flexilis*, originally not present in the area, appeared and spread, especially after the draining and refilling of the ponds. The disappearance of emergent vegetation was followed by an increase in planktonic algae, except in those ponds where there were dense beds of *Chara*. No doubt, in these latter, intense competition for available salts suppresses the growth of the algae. Ponds with unstable bottoms and muddy water differed in that both submerged macrophytes and planktonic algae tended to be suppressed, probably due to the extreme turbidity of water. There is some evidence that in limed ponds, submerged macrophytes, particularly *Chara*, give way eventually to beds of *Enhydrias angustipetala*, and this process is hastened by the application of artificial fertilizers such as potassium chloride – ammonium phosphate mixture, which is being tried out.

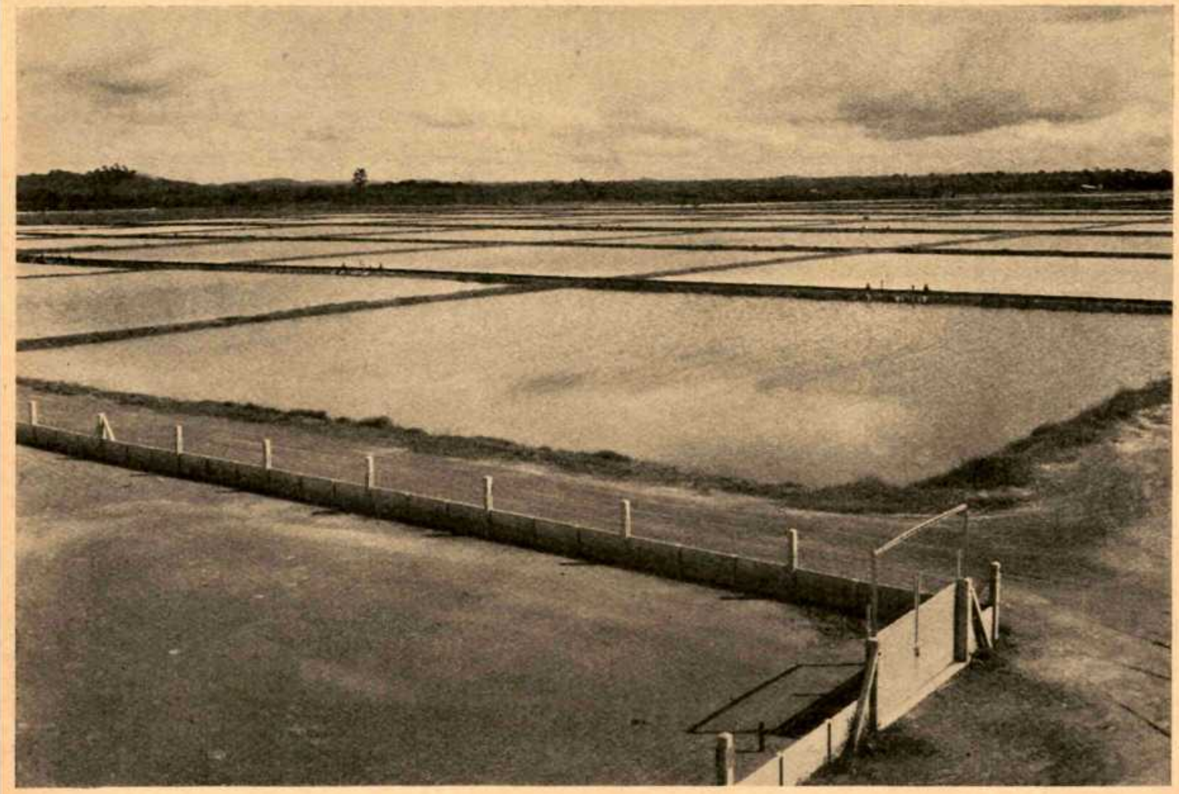

Fig. 2. Fish ponds at the Fish Culture Research Station, Malacca

As yet, a study of fodders, to supplement the food naturally produced for the fish in the ponds, has not passed beyond a preliminary study of the digestive enzymes of fish, and of that part of the natural food which is utilized by the fish. But undoubtedly this work will lead on to a study of cheap fodders, chiefly oil-cake residues, and finding out what part of these can be utilized. The final object of this line of work would be something approaching a balanced ration, taking into account not only the added fodder, but also the natural food supply. This has been done for fish-ponds in temperate climates, but not under tropical conditions.

The Station holds stocks of the following species: *Tilapia zillii* from East Africa; *T. mossambica*, local; *Tilapia* sp. from Zanzibar and hybrids of these *Tilapia* species; *Cyprinus carpio*, common carp, local; *Puntius javanicus*, supplied by the Fisheries Department of the Federation of Malaya; *Catla catla*, from Calcutta; *Osphronemus olfax*, the giant gouramy, local; *Trichogaster pectoralis*, Sepat Siam, local; *Ctenopharyngodon idellus*, the Chinese grass carp, from China.

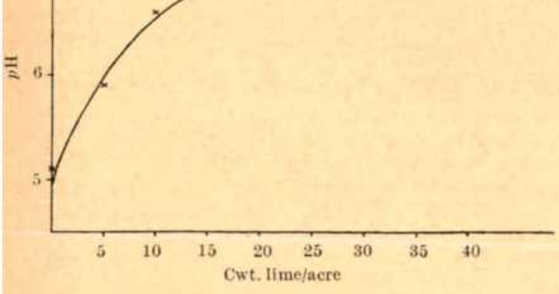

Fig. 3. Effect of lime on pH. Approximate conditions after 100 days

Stocks of the last-named fish are being held against the visit of Dr. H. D. Slack, who, on the basis of work now being carried out by him in the Department of Zoology, University of Glasgow, supported out of Colonial Development and Welfare Funds and by the Nuffield Foundation, hopes to induce them to spawn in captivity. This valuable fish has never spawned in fish-ponds; the fry have to be imported, chiefly from Canton.

Chief interest at present centres on the *Tilapia* hybrids. The Malayan stock of *Tilapia mossambica* is very inbred, and the cross with new stock from East Africa not only has, as might be expected, great vigour and strength; but also certain crosses give a very skew sex-ratio, indeed up to 100 per cent males; and a marking experiment just ended indicates that the cross-bred fish may grow twice as fast as either the Malayan or the African parent stocks. An extremely promising field is open here; for a fish of very rapid growth, but which cannot breed in the rearing ponds, comes very close to the ideal pond-fish for commercial or subsistence raising.

OBITUARIES

Prof. Niels Bjerrum

We regret to record the recent death of Niels Bjerrum. He was born in Copenhagen on March 11, 1879, and studied in the University there, taking the degree of Dr. Phil. in 1908 and presenting a dissertation on the hydrolysis of chromium compounds. This work was extended by the discovery of the third isomeric hexahydrate of chromic chloride and, as a result of a study of the absorption spectra of solutions of chromic salts, by the provision of an experimental foundation for the hypothesis of the complete dissociation of strong electrolytes in solution, which Bjerrum in 1909 was the first to make really significant.

Bjerrum later published many valuable researches in various branches of electrochemistry, the theory of acids and bases, the measurement of hydrogen ion concentrations, amphoteric electrolytes, and the behaviour of indicators. He published a monograph on acid-alkali titration and discovered a simple method of eliminating diffusion potentials in measurements of hydrogen ion concentrations. His work in this field had a very significant influence on the development of the modern theory of electrolytes. He developed a simple equation connecting the activity and osmotic coefficients of an electrolyte, and another one relating the activity coefficients to reaction velocity. He worked with Perrin in 1911 on the Brownian movement and later published work on colloid chemistry. In 1923, he published an important paper on the relation of the stages of ionization of polybasic acids to the molecular structure. In 1911, he related the specific heats of steam and carbon dioxide to band spectra. In 1912, he published work with Nernst on the specific heats of steam and carbon dioxide at high temperatures as determined by the explosion method, and in 1914 he laid the foundations of the theory of the infra-red spectra of polyatomic molecules by introducing the so-called valency force-field, which has led to all subsequent developments in this subject. In these publications he applied the newly developed quantum theory of specific heats to gases.

In 1914, Bjerrum became professor of chemistry in the Royal Danish Veterinary and Agricultural College in Copenhagen, an institution which has had a distinguished history. Since then he has published a large amount of important work in various branches of inorganic and physical chemistry and on problems in agricultural chemistry, notably on the factors which determine the *p*H of soils and their fertility. He wrote an excellent small text-book on inorganic chemistry which has gone through several editions, including two in an English translation.

In his prime, Niels Bjerrum was a tall man of handsome presence with an open and friendly expression, and a calm dignity of manner. He will be greatly missed by his many friends in all parts of the world.

J. R. Partington

Prof. D. C. Grahame

David Caldwell Grahame, professor of chemistry at Amherst College, Amherst, Massachusetts, U.S.A., died suddenly as a result of a coronary thrombosis in London on December 11. He was spending the academic year as a visiting professor in the University of Bristol.

Prof. Grahame was born in St. Paul, Minnesota, on April 21, 1912. He received a bachelor's degree in chemical engineering at the University of Minnesota in 1935 and a Ph.D. degree in physical chemistry at the University of California at Berkeley in 1937. From then until 1939 he was an instructor in chemistry at Berkeley. From 1939 he was on the staff at Amherst College, becoming assistant professor in 1942, associate professor in 1947 and professor in 1953. He received an honorary M.A. from Amherst in 1953. In 1945 he was a member of the staff of the Radiation Laboratory, Massachusetts Institute of Technology. He taught at Harvard in the summer of 1948. He had visited Europe on several occasions since 1952, having been invited to present papers at meetings of the Deutsche Bunsengesellschaft (1955) and the Chemistry Section of the Soviet Academy of Sciences (1956). He held a Guggenheim Fellowship during his stay in Bristol.

His scientific work was largely in the field of electrochemistry, particularly in the study of the electrical double layer located at the interface between a metal and an electrolytic solution. He developed an accurate method of determining the properties of this double layer by measuring its electrical capacity with an alternating current bridge using a growing drop of mercury or gallium as electrode. With this elegant technique he obtained precise results for an extensive variety of electrolytes. Starting from the basic thermodynamic principles, he showed how these results could lead to accurate values of the ionic concentrations at the surface of the electrode and hence to a reliable picture of the structure of the interfacial region. He gave a lucid and comprehensive account of the theory of this procedure in *Chemical Reviews* in 1947, which was further developed in his paper with Barbara Sodernerg in the *Journal of Chemical Physics* in 1954.

More recently, Prof. Grahame had turned to the adsorption of poly-electrolytes and the use of non-aqueous solutions. In recent months he had devoted much attention to a study of the distribution of potential in the region within a few Ångströms of the surface of the metal. The progress he made in elucidating the latter was only possible on the basis of the precise experimental work in which he excelled, together with the depth of his insight into the theoretical aspects of the problem. It is regrettable that this work remains incomplete.

David Grahame's cheerful friendliness won him friends in all parts of the world, all of whom must grieve at his early death. He was married in 1935 to Virginia Dakin, who survives him, with a son and a daughter.

R. Parsons

Prof. William Brunner

On December 1 William Brunner, emeritus professor of astronomy in the University of Zurich and the Swiss Federal Institute of Technology, died in Zurich. Brunner was born in Wattwil (Switzerland) on July 8, 1878. In 1900—after having been a merchant for some years—he began studying astronomy at the Swiss Federal Institute of Technology in Zurich, where in 1904 he acquired the diploma in mathematics and physics. During the next twenty-two years he was a teacher in a girls' college, until in

1926, in succession to Prof. A. Wolfer, he was appointed director of the Swiss Federal Observatory and at the same time professor of astronomy in the Institute and in the University of Zurich; both directorship and professorship he occupied until, for reasons of health, he retired in 1945.

Besides lecturing, Brunner carried on the traditional work of the Swiss Federal Observatory, namely, the observation of sunspots. In thirty numbers of the *Astronomische Mitteilungen* and in two volumes of the *Publikationen der Eidgen. Sternwarte* he published the yearly reports on solar activity, which contain above all the relative sunspot numbers as a continuation of the series reaching back to the year 1749, but also articles on the development of sunspot groups and on the prominence statistics. In 1928 the International Astronomical Union handed over to him the publication of the *Quarterly Bulletin on Solar Activity*. During the years 1938–45 he was a member of the executive committee of the International Astronomical Union.

Brunner wrote several popular books, among them "Die Welt der Sterne" and "Pioniere der Weltallforschung". On his retirement in 1945 he was elected an Associate of the Royal Astronomical Society of London.

M. WALDMEIER

NEWS and VIEWS

Forestry Division of the Food and Agriculture Organization: M. Leloup

M. MARCEL LELOUP, director of the Forestry Division of the Food and Agriculture Organization of the United Nations since its creation twelve years ago, is retiring. M. Leloup was a veteran of the First World War and a recipient of the Légion d'Honneur after losing an arm during the battle of Verdun. Having graduated from the famous École Polytechnique, he began his forestry career with the Colonial service of the French Department of Waters and Forests in French Equatorial Africa. In 1932 he returned to Paris to the general direction of the Department of Waters and Forests. In 1936 he was assigned to the Presidence du Conseil and charged with several special missions concerning agricultural and administrative matters. It was in this capacity that he collaborated in the establishment of the Statute of Public Function and was nominated to the highest French administrative body, the Council of State. After the Second World War, M. Leloup became director-general of the Department of Waters and Forests and a Councillor of State. Shortly afterwards he was a member of the French delegation to the Quebec conference of 1945, at which the Food and Agriculture Organization was founded. In May 1946 he became the first director of its Forestry Division. The wide organizational work which he accomplished in this capacity gave him an exceptional knowledge of the problems and possibilities of forests in the world, and he was active in the formation of the Regional Forestry Commission for Europe (1947), for Latin America (1948), for Asia and the Far East (1949) and for the Near East (1953).

E. Glesinger

MR. EGON GLESINGER, formerly deputy director, became director of the Division of Forestry and Forest Products, the new title of the Forestry Division, on January 1. Mr. Glesinger was born in 1907 and was educated in Austria and Czechoslovakia. He graduated in commercial science at Geneva in 1927, obtained a doctorate of law at Prague in 1929 and a doctorate in political science at Geneva in 1932. He also studied at the Institute for International Studies at Geneva, and his thesis on European forests was afterwards published in book form. During 1933–38, Mr. Glesinger was director of the International Timber Committee, an organ of the League of Nations situated first in Vienna and later in Brussels. After the Second World War, he served on the Interim Commission which preceded the formal establishment of the Food and Agriculture Organization, and has been an official of the Organization since its foundation. Besides his post as deputy director of the Forestry Commission, he is at present director of the Timber Division of the United Nations Economic Commission for Europe.

Canadian National Aeronautical Establishment

THE creation of a new Division of the National Research Council of Canada, to be known as the National Aeronautical Establishment, has recently been announced. The formation of the National Aeronautical Establishment was initially authorized in 1951, when it consisted of the aeronautical research facilities of the Division of Mechanical Engineering in the National Research Council, but the heavy and increasing demands on the Establishment have rendered it administratively expedient to separate it from the present Division of Mechanical Engineering, and embody it in a separate Division. The resources of the new Division will consist of the Flight Research Hangar and laboratories at Uplands Airport, the new 5-ft. supersonic wind-tunnel now being constructed at Uplands Airport, and the Aerodynamics and Structures Laboratories in the Montreal Road Laboratories of the National Research Council. The new Establishment will work on defence problems in aeronautical science, and will also be responsible for meeting the aerodynamic and structural research needs of civil aviation and of the aircraft industry.

Mr. F. R. Thurston

MR. FRANK R. THURSTON, head of the Structures Laboratory of the Division of Mechanical Engineering, who has been appointed acting director of the National Aeronautical Establishment, was educated in the United Kingdom, graduating from the University of London. He went to the National Research Council in 1947 from the National Physical Laboratory, Teddington, where he worked on supersonic aerodynamics and on the structural design of aircraft. In the National Research Council he has been responsible for the structural proving of prototype Canadian-built aircraft, and for a wide range of research on structural fatigue, towers and shell structures, and aircraft hydraulic equipment. Representing Canada, Mr. Thurston is chairman of the

Structures and Materials Panel of the Advisory Group for Aeronautical Research and Development of the North Atlantic Treaty Organization and works as a co-ordinator for the Commonwealth Advisory Aeronautical Research Council.

Royal Geographical Society : Medals and Awards, 1959

H.M. THE QUEEN has approved the award of the Royal Medals of the Royal Geographical Society, as follows: *Patron's Medal:* Commander W. R. Anderson, U.S.N., for the first trans-polar submarine voyage, in command of U.S.S. *Nautilus*; *Founder's Medal:* Sir Raymond Priestley, British observer, U.S. Antarctic Expedition, 1958–59, for services to Antarctic exploration.

The Council of the Royal Geographical Society has made the following awards: *Victoria Medal:* Mr. Gerald Seligman, president of British Glaciological Society, for contributions to glaciological research; *Murchison Grant:* Prof. S. P. Chatterjee, professor of geography, Calcutta, for important work organizing and directing the "National Atlas of India"; *Back Grant:* Mr. David Stratton, deputy-leader, Commonwealth Trans-Antarctic Expedition; *Cuthbert Peek Grant:* Mr. W. George Lowe, for contributions to Himalayan and Antarctic exploration; *Gill Memorial:* Mr. G. S. Holland, chief draughtsman, Royal Geographical Society, for contributions to cartography, especially of southern Arabia; *Mrs. Patrick Ness Award* (jointly): Mr. J. H. Miller, deputy-leader, New Zealand party, Commonwealth Trans-Antarctic Expedition, for contributions to Antarctic exploration, and Dr. George W. Marsh, Commonwealth Trans-Antarctic Expedition and Falkland Islands Dependencies Survey, for contributions to Antarctic exploration.

British National Committee on Antarctic Research

THE British National Committee on Antarctic Research has been set up to co-ordinate British Antarctic activities in relation to the large scientific programme at present being considered by the Special Committee on Antarctic Research of the International Council of Scientific Unions. This programme includes meteorology, ionospheric studies, auroral physics, geomagnetism, cosmic rays, geology, glaciology, geomorphology, cartography, seismology, gravity, vulcanology, oceanography, sea ice, biology including marine aspects and physiology. The members of the new National Committee are: *Chairman*, Sir Raymond Priestley; Royal Society: Prof. W. V. D. Hodge, Sir Lindor Brown, Dr. H. G. Thornton, Mr. A. H. Sheffield, Prof. F. W. Shotton, Prof. J. E. Smith, Dr. R. L. Smith-Rose, Dr. R. Stoneley and Sir James Wordie; Sir Vivian Fuchs, scientific director, Falkland Islands Dependencies Survey; Brig. M. Hotine, director, Overseas Surveys; Rear-Admiral K. St. B. Collins, hydrographer of the Navy; Dr. G. E. R. Deacon, director, National Institute of Oceanography; Sir Graham Sutton, director-general, Meteorological Office; Dr. G. de Q. Robin, United Kingdom delegate to the Special Committee of Antarctic Research; Sir Miles Clifford, Royal Geographical Society; Dr. E. Hindle, Royal Geographical Society; Mr. G. Seligman, British Glaciological Society; Dr. S. Evans, Scott Polar Research Institute; Mr. J. Paton, Royal Society of Edinburgh; Dr. L. G. C. E. Pugh, Medical Research Council; and Mr. H. H. Lamb, Royal Meteorological Society.

Safety and the Nuclear Power Industry

THE hazards which nuclear power stations present were raised by Mr. G. Roberts in an adjournment debate in the House of Commons on January 21. In reply, Sir Ian Horobin, Parliamentary Secretary to the Ministry of Power, said that on the best evidence available there is no danger of radioactive strontium from nuclear power stations in areas of high rainfall like north-west Wales adversely affecting the water supply. Further, although the amount of radioactive strontium descending from the stratosphere is increasing at the present rate, it will be several generations before the equilibrium-level built up in the bones of the population reaches the amber band. The increase in leukæmia began a generation before the first nuclear tests, and there are at present no statistically significant differences, either by area or in time, in the incidence of this disease; specifically there is no statistical difference between north Wales and other parts of the United Kingdom. In the normal operation of a nuclear power station certain radioactive substances might go up the stack but their life is so short that they can be ignored, as can seepage. As regards the release of coolants, monitoring is done with such extreme care that hazard is unlikely. The Wigner type of release which led to the Windscale accident will not be necessary in the new stations where the coolant, carbon dioxide, will operate in a closed circuit. Sir Ian thought that only in very exceptional circumstances could an accident lead to serious contamination and assured the House that Britain is in the forefront not only of constructional ingenuity but also in safety devices in this field.

Glass in Nuclear Research

IMPORTANT developments in nuclear research in recent years have meant an increased demand for viewing windows to permit clear observation of operations or objects within the bounds of the 'hot' cell walls, and also to facilitate the remote handling of radioactive materials, while providing protection for the operatives. Just as ingenious mechanisms have been evolved for remote handling, so have special types of glass been produced for shielding windows. The Chance-Pilkington Optical Works, at St. Asaph, North Wales, has now developed radiation-absorbing glasses of larger dimensions than have been available hitherto in Europe. Particularly at very short wave-lengths, the attenuation offered by protective walling is proportional to the density of the material employed. The Chance-Pilkington shielding glasses range in density from 2·5 gm. per c.c. to 6·1 gm. per c.c., and allow the design of windows to be, in many cases, of equal thickness to the surrounding wall, thereby reducing the complexity of additive shielding and obtaining the maximum optical advantage from the window.

Upon receipt of large doses of short wave-length radiation, glasses of normal composition tend to discolour to a deep yellow or brown. To overcome this, Chance-Pilkington manufacture a series of glasses which are stabilized. These glasses have amended compositions having the effect of slightly decreasing the transmission of the glass in the unirradiated state, but reducing the tendency for further discoloration under conditions of radiation. Shielding glasses of density 2·5 gm. per c.c. and 4·3 gm. per c.c. are manufactured in polished plate form and also in block form up to 4 ft. 6 in. by 3 ft. in area and 10 in. in thickness, with the limitation for the time being that no single block shall weigh more than 2,000 lb.

New Process of Making Plate Glass

PILKINGTON BROTHERS, LTD., of St. Helens, Lancashire, have just announced the successful development of a new process of making plate glass. In the new process the plate glass is produced with a fire-polished finish, so that the lengthy grinding and polishing operations which are necessary with the present method of producing plate glass are eliminated. The crux of the process which contains the revolutionary idea is that the molten ribbon of glass, which flows from the usual tank furnace containing the molten glass through a pair of rollers, is then supported on the surface of a bath of liquid metal. This is at a sufficiently high temperature for the under-surface of the glass to take up the extreme flatness of the surface of the liquid metal while at the same time the top surface can be subjected to sufficient heat to produce a good fire polish. This new operation takes place in a chamber containing a controlled atmosphere. Pilkingtons have named the new process the 'float process' and are referring to the new product as 'float glass'. Ordinary window glass, known in the industry as sheet glass, is also produced with a fire-polished surface by drawing upwards from the surface of a bath of molten glass, but the quality of this type of glass is not sufficiently good for its use in motor-car windows, shop windows, or for the preparation of mirrors, and it is for applications of the kind just mentioned that plate glass is in demand. The growth of the motor-car industry has, of course, made the demand for plate glass rise steeply, and this invention is thus a very timely one.

The history of the manufacture of plate glass can be seen to follow a pattern in recent years of the gradual development of an existing process until a fundamentally new idea occurs. About the beginning of the first century A.D., flat glass was first made by the crown process, in which a flat disk of glass was spun on the end of an iron. The method of making sheet glass by fabricating a cylinder which was then split and flattened was first described in about A.D. 1100; the casting and rolling process of making plate glass was invented in France towards the end of the seventeenth century. In 1910 the cylinder method was mechanized and cylinders up to 40 ft. long and 6 ft. in diameter were made. Mechanical production of sheet glass by drawing flat sheets of glass directly from a tank was first effected in Belgium just before the outbreak of the First World War, and in 1920 the continuous flow process of plate glass manufacture was developed in the United States. Pilkingtons have largely been concerned in the development of this process, leading to the famous twin-grinding machine, which grinds and polishes both sides of the glass simultaneously. In the light of this background, it can be seen that this new invention is justifiably described as revolutionary.

Cambridge Instrument Co., Ltd.: New Research Laboratory

CONSTRUCTION has commenced of the new Research Laboratory for the Cambridge Instrument Co. Overlooking the River Cam and Jesus Green, and within ten minutes walk of the centre of Cambridge, the 20,000 sq. ft. building will provide an imposing frontage for the Cambridge factory. The top floor with generous roof lighting will form an ideal design and drawing office, and the three floors below are being fitted with the latest equipment for instrument work involving physics, chemistry, electronics and precision mechanical engineering. The new building heralds a considerable expansion in research, development and design for which staff are now being recruited. The architects are Messrs. Edward D. Mills and Partners, designers of the British Industries Pavilion at the Brussels Universal and International Exhibition, 1958, and Messrs. J. Jarvis and Co. are the main contractors. The new Laboratory is scheduled for completion in June.

Iron and Steel at the Science Museum

A NEW exhibition on the principles underlying the manufacture of iron and steel will be opened by Lord Mills, Minister of Power, on February 6 at the Science Museum, South Kensington. Exhibits have been drawn from the Museum's own collections and contributed by makers and users of iron and steel, by other museums and individual donors, to illustrate the development of that industry from its earliest beginnings. By far the largest contribution has been from the British Iron and Steel Federation, which has not only provided a large number of new exhibits but also financed the whole project. Only outstandingly important technological aspects and developments can be touched upon in a limited space—direct reduction of iron ore, charcoal-blast pig-iron and its fining to malleable iron, coke-iron, foundry work, puddling, crucible steel and cementation, modern blast-furnace practice, Bessemer, open hearth and alloy-steel making and modern methods of casting, forging, rolling, drawing, together with theoretical metallurgy, testing and research. The treatment is not exhaustive but provides an excellent stimulus to further study.

British Association: Granada Lectures

A NEW series of annual lectures, organized by the British Association for the Advancement of Science and sponsored by Granada TV Network, Ltd., on the theme of "Communication in the Modern World", has been announced. The broad purpose of these lectures is to explore the impact of communications in the field of the mass media—Press, radio, television and film—in their sociological, political and technical aspects. The first series of three lectures will be given in London in October 1959: the first by Sir Edward Appleton, who will speak on the significance for society of long-range communication and the exploration of space; the second by Dr. Edward R. Murrow, the American television and radio commentator and news analyst, who will speak on the impact of television and radio in the field of politics and public affairs in a democracy; the third by Sir Eric Ashby, whose subject will be methods of presenting scientific information to the man in the street and the extent to which the part played by the mass media in this field might be extended or improved. The lectures will be delivered to an invited audience, to include representatives of science, industry, politics, education, local government, the mass media and others. There will also be a limited number of tickets available to the public. The texts of the lectures will afterwards be published. With each lecture will be linked a television programme, in which it is hoped the lecturer will participate, dealing with the subject-matter of the lecture in appropriate television form for a wider audience.

Synthetic Quartz Crystals

THE Western Electric Company and the Bell Telephone Laboratories in New York have jointly succeeded in growing large crystals of artificial quartz by a process which they hope to develop on a technical scale. It has long been known that small quartz crystals can be developed in silicate solutions by suitable treatment, but in the new process crystals up to 5–6 in. long and 2–3 in. cross-section have been obtained. The method consists in filling a vertical autoclave with an alkaline solution, usually of sodium hydroxide. Small pieces of natural quartz are placed in the bottom to serve as material and high-quality sand will, it is expected, be used in future. Seed plates cut from natural or artificial quartz crystals are hung from a rack in the upper part of the vessel. After sealing, the autoclave is heated to the required temperature and maintained with a constant temperature differential from bottom to top during the processing time, which has varied from a week to several weeks. Growth occurs primarily in one dimension and flat plates are used, which become thicker but change little in other dimensions. The nutrient material dissolves in the hotter lower region and is carried by convection currents to the cooler upper region, where the solution becomes supersaturated and the dissolved silica is deposited in the form of a single crystal. The combination of conditions of high temperature and pressure in the autoclave is severe and the effective sealing of the autoclave has presented a number of problems in the selection of material and design. The crystals produced have no foreign inclusions, can be obtained without optical or electrical twinning, and can be sawn in the most efficient manner.

The Night Sky in February

NEW moon occurs on Feb. 7d. 19h. 22m. U.T., and full moon on Feb. 23d. 08h. 54m. The following conjunctions with the Moon take place: Feb. 2d. 01h., Jupiter 3° S.; Feb. 4d. 12h., Saturn 4° S.; Feb. 16h. 05m., Mars 6° N. Mercury is too close to the Sun for observation. Venus is an evening star, visible in the south-west after sunset. It sets at 18h. 30m., 19h. 10m. and 19h. 55m. on February 1, 15 and 28, respectively; its stellar magnitude is $-3{\cdot}3$. Its distance decreases during the month from 146 to 137 million miles, and the visible portion of the apparent disk decreases from 0·945 to 0·900. Mars is moving eastwards among the stars and is in Taurus during February. It sets at 2h. 45m., 2h. 25m. and 2h. 05m. at the beginning, middle and end of the month, respectively. Its stellar magnitude decreases from $+0{\cdot}3$ to $+0{\cdot}8$, its distance from the Earth increasing from 94 to 119 million miles. Mars is well placed for observation during the evening. Jupiter rises at 2h. 45m., 2h. 00m. and 1h. 10m. on February 1, 15 and 28, respectively; it is in Libra. The stellar magnitude of Jupiter is $-1{\cdot}6$; conditions for observation are not very favourable. Saturn is a morning star in Sagittarius, rising at 5h. 35m., 4h. 45m. and 3h. 55m. at the beginning, middle and end of the month, respectively. It is unfavourably placed for observation. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Feb. 17d. 21h. 43·6m., 115 Tau. (*D*); Feb. 18d. 18h. 20·9m., 124 H^1 Ori. (*D*); Feb. 20d. 0h. 23·0m., λ Gem. (*D*); Feb. 21d. 19h. 14·2m., α Cnc. (*D*). *D* refers to disappearance.

Announcements

SIR JOHN COCKCROFT has accepted the invitation of his fellow Trustees of the future Churchill College, Cambridge, to become its first Master. Future Masters of the College will be appointed by the Crown on the advice of the Prime Minister.

LIFE peerages (baronies) have been conferred on the following: Sir Eric James, high master of Manchester Grammar School; Sir Edwin Plowden, chairman of the United Kingdom Atomic Energy Authority; Prof. Lionel Robbins, professor of economics in the University of London; and Sir Hartley Shawcross, the distinguished lawyer.

PROF. R. G. BASKETT has been appointed director of the National Institute for Research in Dairying, University of Reading, as from August 1, 1959.

DR. T. S. ENGLAND has been appointed head of airborne radar at the Royal Radar Establishment, Malvern, as from January 1.

THE New York Academy of Medicine has awarded its Medal to Dr. Peyton Rous for his contributions to knowledge of neoplastic disease. The Academy has awarded its Plaque to Mr. Montgomery B. Angell, for outstanding service to the New York Academy of Medicine as its legal adviser.

THE first of the new afternoon lectures for sixth-form children from schools in London and the Home Counties were delivered at the Royal Institutio Albemarle Street, London, W.1, on January 27 and 2 by Mr. E. Jenkins (Atomic Energy Research Establishment, Harwell), who spoke on "Radioactive Elements". This lecture is to be repeated on February 3 and 4. The programme of lectures for the remainder of the term is as follows: "The Origin of Man", by Prof. J. Z. Young, on February 10, 11, 17 and 18; "The Significance of Colour in Inorganic Chemistry", by Prof. R. S. Nyholm, on February 24 and 25 and March 3 and 4 (sponsored by the Salters' Company); "Electrons in Solids", by Prof. R. King, on March 10, 11, 17 and 18 (sponsored by the Bell Telephone Laboratories).

THE American Society of Mechanical Engineers, in co-operation with Purdue University Thermophysical Properties Research Center, is organizing a symposium on "The Thermal Properties of Gases, Liquids and Solids", to be held at Purdue University, Lafayette, Indiana, during February 23–26. Further information can be obtained from Prof. R. A. Olsen, School of Mechanical Engineering, Purdue University.

THE Seventh Latin American Congress of Chemistry will be held in Mexico City during March 29–April 3. On the afternoons of April 1 and 2 an international symposium will be held on "Recent Progress in Organic Chemistry". The morning sessions during these two days will be devoted to about twenty shorter papers dealing with steroids and related natural products. Further information can be obtained from Dr. Alberto Sandoval, Instituto de Quimica, Ciudad Universitaria, Mexico 20, D.F.

ERRATUM. Dr. S. Bricteux-Grégoire states that there was a mistake in the manuscript entitled "Utilization of Formate for the Biosynthesis of Glycine Carbon-1 and -2 in *Bombyx mori*", published in *Nature* of November 29, p. 1515. In Table 1, for "C-1, 20,300 and C-2, 43,500", read "C-1, 43,500 and C-2, 20,300".

ZOOLOGY IN NIGERIA

ECOLOGY OF LAGOS LAGOON

THE University College of Nigeria has achieved a standing among the university institutions of the Commonwealth which few even among the most visionary spirits would have dared to hope for at the time of its foundation little more than ten years ago in a forest clearing at Ibadan. Students recruited from a country where there are few secondary schools have been enabled to pursue courses for honours degrees in a wide range of subjects and disciplines within the Faculties of Arts, Science, Agriculture and Medicine, and the standards achieved by them are those which the University of London, with which the College is in special relationship, requires of its honours students. That the College should have produced a body of graduates ready to take their places as administrators and teachers in a country soon to achieve independence is a tribute alike to the innate abilities of the Nigerian student and to the sound and imaginative teaching of the professors and lecturers who, over the years, have staffed the several departments of the College. Nor in these formative years has the prosecution of research been neglected and there has recently been published, in the *Philosophical Transactions of the Royal Society*, a series of papers[*] by Prof. J. E. Webb (two of them jointly with Dr. M. B. Hill), of the Department of Zoology, which will exemplify the kind of work which is being done and which, while born of and descriptive of West African conditions, probes deeply and with discernment into problems of fundamental and more general biological interest.

The papers are concerned primarily with the life-history and ecological requirements of the Nigerian lancelet, *Branchiostoma nigeriense* Webb, one of the many species contained within the group of the Cephalochordata the structure and development of which show them to stand very close to the ancestral stock of the vertebrates. The observations range in their scope from considerations of physical geography and coastal morphology to an analysis of the significance to animals of the size and shape of sand grains, without, however, ever losing its essential unitary character as an ecological investigation.

Lagoon systems occur on the Guinea Coast, within the general areas of the Ivory Coast, Togoland and Dahomey–Western Nigeria. They are formed behind barrier beaches of sand, the sand drifting from west to east along the beaches and offshore under the action of obliquely breaking waves developed under the predominantly south-westerly winds. Lagoons are formed by the seaward advance of the barrier beach or by enclosure by outwardly growing spits curved at the tips to form offshore bars. The lagoons may remain filled with water by virtue of river drainage or access to the sea. There is, however, a tendency for them gradually to fill with sediment, first to become swamps and then dry land. Aerial photographs show that the cycle has been repeated many (about twenty) times in the 25,000 years of the post-glacial history of the Guinea Coast. Narrow bands of sparse vegetation alternating with broader zones of more luxuriant growth mark, respectively, the lines of former sand barriers and of lagoon deposits.

The Lagos lagoon system is open to the sea by narrow channels and receives the drainage water from some 40,000 square miles of forest country. In the drier months from December to March higher salinities rising from about 10 to 30 per mille prevail, whereas with the coming of the rains the salinity falls sharply to give brackish or fresh conditions which tend to persist with brief intermissions from about April to December. It is against this background of changing salinities that the appearances and disappearances of *Branchiostoma* within the waters and bottom deposits of the lagoon must be viewed.

Laboratory experiments show that the lancelets tolerate changes in temperature greater than those normally encountered within the lagoon but that they die in less than a day's immersion in water of less than 13 per mille salinity. They are, in fact, absent from the lagoon from about mid-May to mid-December, when the salinity is 13 per mille. By mid-December conditions are again favourable for restocking of the lagoon from the persistent populations of lancelets of the outside waters. These latter were found to spawn from about August to October and to give rise to pelagic larvæ ready to seek the bottom and to metamorphose at the earliest some eleven weeks after fertilization, a tally being kept of the length of the larvæ and of the number of their gill pouches at the different ages. Larval life can be extended to twenty weeks or so if a suitable substratum is not available for settlement. Re-population of suitable lagoon deposits can then begin at the moment that the rise in salinity of the lagoon water permits of survival of larvæ drifted in from the sea. Once settlement has been achieved, the lancelets remain in the deposits until killed off in May by the fall in salinity following upon the onset of the March rains. In the meantime, a few of the resident population will have spawned: the young are, however, short-lived, being killed by the influx of fresh water while still in the pelagic phase or shortly after metamorphosis.

The various aspects of these successive events are examined in detail. None is of more interest than the observations and experiments which bear on the substratum requirements of the metamorphosing and adult lancelets. In Nature, animals only occur in coarse sand containing 25 per cent of particles smaller than 0·2 mm. in diameter and in which the finer silts bulk less than 1·5 per cent. While, in laboratory tests, a few animals would settle in soils containing rather more of the fine sand or of the silt, they did not long remain viable. Moreover, it was only in the coarse, open sands that they burrowed normally; in mixtures of progressively finer particles they remained partially buried or rested on the surface. But particle-size is not all. Smooth-grained mixtures are sought after, sharp particles avoided; again, sands with silt or organic matter in excess of a certain amount are not favoured, but neither are those which lack micro-organisms on the surfaces of the grains. It is shown that the particular size-range of particle mixtures chosen by the lancelets are those with a high porosity, that is to say, they have a system of canal spaces within which water may circulate freely.

---

Webb, The Topography and Physical Conditions of Lagos Harbour and Lagos Lagoon, pp. 319–334; III, J. E. Webb, The Life History of *Branchiostoma nigeriense* Webb, pp. 335–353; IV, M. B. Hill and J. E. Webb, On the Reactions of *Branchiostoma nigeriense* Webb to its Environment, pp. 355–391; V, J. E. Webb, Some Physical Properties of Lagoon Deposits, pp. 393–419.

Thus, in the event, the lancelets select substrata by their texture, but benefit by other properties dependent on texture, such as free drainage.

The community concept, in so far as it applies to animals living in the deposits of the ocean floor, has long been known to be founded upon the selection by animals of soils of varying texture and particle size. Few investigations in recent years have been more revealing of the bases of this selection than those described in the last of the five papers here reviewed.

J. E. SMITH

IMMUNOLOGICAL ASPECTS OF ALLERGIC DISORDERS

"IMMUNOLOGICAL Aspects of Allergic Disorders" was the subject of the symposium of the autumn meeting of the British Society for Immunology, held jointly with the British Association of Allergists, at the Wellcome Building, London, on November 14.

A. W. Frankland introduced the subject as a clinician engaged in the treatment of 'allergic' disorders, for which antigen-antibody reactions are considered responsible. Seasonal pollen asthma, the least complicated allergic disease, responds equally well in 90 per cent of subjects to pre-seasonal treatment with a high dosage of an extract of the pollen of a single grass as with extracts of mixed grass, illustrating the need for studies of pollen antigens. A beneficial effect, however, is also found in between one-third and one-half of the patients treated with saline injections.

The significance of reactions to skin tests showing the presence of reaginic antibodies capable of sensitizing the skin requires clinical confirmation. In 50 per cent of subjects sensitive to pollen skin tests, observed over a period of ten years, clinical sensitivity does not appear to become important. Inhalation tests may confirm the presence of clinical sensitivity.

The clear description of allergic reactions is desirable. Immediate reactions are seen in pollen sensitivity; delayed reactions are of the tuberculin type. An unexplained relationship between these is present in reactions to insect bites. The first bites are usually innocuous, but after a time they may excite reactions of the delayed type. At a later stage, reactions of the immediate type appear, and still later, in some cases, there may be a complete absence of reaction to the bites.

R. Augustin, in a paper entitled "Allergens and other Pollen Antigens", reported her investigations into the relationship of grass pollen antigens, which excite in rabbits the production of precipitating antibodies, and those grass pollen antigens, which are allergenic for man, reacting with the reaginic but non-precipitating antibodies which sensitize the skin, as shown by reactions to skin tests. The complicated pattern of antigen-antibody precipitation lines produced in agar-gel diffusion tests with rabbit antisera were studied for their relevance to allergenic activity in skin tests on man. Enzymic and other studies showed that the antigens of timothy and cocksfoot pollen that were most highly electrically charged were not significantly related to skin-test allergens. The main allergens were found in those antigens having the electrophoretic mobilities and salting out properties of human serum α- and β-globulins. These antigens, on one hand, were precipitated with rabbit antiserum and, on the other, accounted for almost all the allergenic activity in man. The concentrated fractions obtained in this way contained 10–100 million Noon units/mgm. (1 mgm. pollen equals 1,000 Noon units by definition). Coupled preparations of this active allergenic material with red cell stromata and hide powder (Baird and Tatlock) were effective in removing, specifically, the reaginic antibodies from the serum, as shown by passive transfer tests, thus providing a method for demonstrating the presence of reagins.

J. G. Feinberg and H. Grayson discussed the results of "A New Look at the Antibodies to so-called 'Common' Antigens of Grass Pollens". Using antibody gradients and eccentric patterns of precipitation, they showed that rabbit antibodies to pollens have a greater affinity for homospecific than for heterospecific pollens. A similar but greater homospecificity is shown with rabbit antisera to ovalbumin and ovalbumin tagged by means of arsenilic acid. It was suggested that pollen treatment should be based on homospecific pollen allergens.

Some observations on the antibodies related to ragweed pollen were discussed by B. Rose, who with Sehon and his colleagues have found that there are four antibodies in the serum of sensitive patients. Erythrocytes coated with antigen provided a highly sensitive and specific method for demonstrating non-precipitating antibodies. Two of the antibodies found were skin-sensitizing, one was a blocking antibody, and one a hæmagglutinating antibody. The blocking antibody was found in the slow-moving γ_2-globulin and the skin-sensitizing antibody in the fast-moving γ_1-globulin. The skin-sensitizing antibody also moved with the fast-sedimenting $S19$ fraction. The hæmagglutinating antibodies are considered to be similar to the ordinary divalent antibodies and were found in all serum fractions containing skin-sensitizing and/or blocking antibodies.

M. Loveless discussed the reproducibility and practical value of the conjunctival test for estimating the degree of hypersensitivity to ragweed pollen. Reactions to increasing concentrations were observed, and a good correlation was found between the degree of hypersensitivity and the titre of blocking antibody present in the serum after treatment by injection. The conjunctival test was used as a guide to the safe dosage of pollen for injection in a 'repository' form, in emulsion of liquid paraffin and 'Arlacel'. Such a guide is necessary since the dosage of pollen in the limited number of injections of repository required is far higher than the initial doses of aqueous extracts used for conventional methods of pollen treatment.

Investigations into allergic hypersensitivity in man to *Aspergillus fumigatus* were described by J. Pepys, R. W. Riddell, K. M. Citron, Y. M. Clayton and E. I. Short. Allergic reactions to the ubiquitous and perennial spores of *A. fumigatus* consist of rhinitis, conjunctivitis and asthma. The fungus also causes respiratory infections, associated with pulmonary eosinophilia, consisting of transient, recurrent pulmonary infiltrations, febrile episodes and eosinophilia of the sputum and blood. *A. fumigatus* is found with a significantly greater statistical frequency in the sputum of asthmatics without pulmonary eosinophilia than in the sputum of patients with other respiratory disorders.

Hypersensitivity as the cause of the pulmonary eosinophilia was investigated. Skin-prick tests with extracts of *A. fumigatus*, *flavus*, *nidulans*, *niger* and *terreus* gave positive reactions to almost all species in nearly every hypersensitive subject. Culture-medium filtrates, one month old, were the most potent allergens, followed by the cell sap of fresh mycelia, and then by conventional carbol saline extracts of dried mycelium.

Prick tests produced immediate weal-reactions, followed after 3–12 hr. in a number of cases by a 'late' reaction. This reaction was occasionally quite extensive and differed macroscopically and in its more rapid appearance and resolution from the delayed tuberculin type of reaction. Histologically it showed early, intense and persistent infiltration of eosinophile cells, as compared with the perivascular infiltration of round cells in the tuberculin reaction. These features and the demonstration of precipitating antibodies in the serum of patients by means of concentrated extracts of *Aspergillus*, especially *A. fumigatus*, suggest that the 'late' reaction is of the Arthus type.

Bronchial reactions to inhalation tests with extracts of *Aspergillus* were most evident in patients with pulmonary eosinophilia. Proof that the fungus plays a part in the clinical picture must rest, however, not only on evidence of its presence in the sputum, but also on immunological confirmation.

Preliminary investigations into the immunochemistry of *Cladosporium* were reported by J. Longbottom, B. Hayward and R. Augustin. Extracts of spores and mycelium were found to be equal in potency in skin tests. Their active components were found, as with pollen, to be non-dialysable and to be associated with the protein-like material which did not move from the base-line in paper chromatography.

At least eight antigens were demonstrable in agar-gel tests with rabbit antisera to *C. fulvum* and *C. herbarum*. Antiserum to *C. herbarum* gave precipitation lines with the antigens of *C. fulvum*, but not *vice versa*. The *Cladosporium* antigens have the mobilities of serum albumins and α- and β-globulins. Of four antigens shown by immunoelectrophoresis in *C. fulvum*, three were found to be non-allergenic in man. Patients tested with the extracts and with proteolytic digests of the two species showed individual variations, as might be expected.

J. F. Ackroyd discussed a patient with allergic thrombocytopenic purpura due to antazoline. Antazoline added to the serum caused lysis of the platelets and the formation of a precipitate, both mediated by the same antibody. Taking the drug on two later occasions resulted in a rise in the fallen antibody titre. Formation of a precipitate at these times was not, as it had been previously, accompanied by complement fixation; and no cause could be found for this.

The observation that the formation of a precipitate with complement fixation was produced by adding the drug to serum, collected while the patient was taking sufficient antazoline to give high enough blood-levels to excite thrombocytopenia, suggests that the union of the drug and the platelets is very labile. This dissociability may explain why so few persons develop purpura on taking antazoline and other drugs such as sedormid, quinine and quinidine, for which a similar lability has been observed.

J. PEPYS

THE NEW FERODO RESEARCH LABORATORIES

By DR. R. C. PARKER

Research Director

ON November 21, some sixty-one years after Mr. Herbert Frood, the founder of Ferodo Ltd., produced his first friction material, H.R.H. the Duke of Edinburgh formally opened the new Research Laboratories of the firm by unveiling a suitably inscribed bronze plaque. Work on current problems was afterwards inspected. In the following week a series of open days were arranged, one of which was reserved for the teaching staffs of universities, local technical colleges and schools and for the staffs of research institutes.

The building (Fig. 1) is in the form of a splayed *E* having a total floor area of 75,000 sq. ft. The upper two stories of the front of the building house the Administration Department, a Plant Development Department and offices for senior managers, while the two-storied centre wing with a floor area of 12,000 sq. ft. houses the Physical, Chemical and Metallurgical Laboratories. All the internal partitions in both laboratories and offices are built on a five-foot module and can be readily mounted or removed as desired. The left-hand wing, covering 21,000 sq. ft., comprises an Engineering Test House, a workshop and a test car garage, and the right-hand wing, with an area of 18,000 sq. ft., contains pilot plant. The site of the building is such that when further space is required the length of the three projecting wings can be increased by 50 per cent. The building is pleasantly situated on the main road from Chapel-en-le-Frith to Hayfield, and is set among landscape gardens.

The main heating of the offices and the laboratories is by warm water that circulates through special steel coils embedded in the ceilings. Supplementing

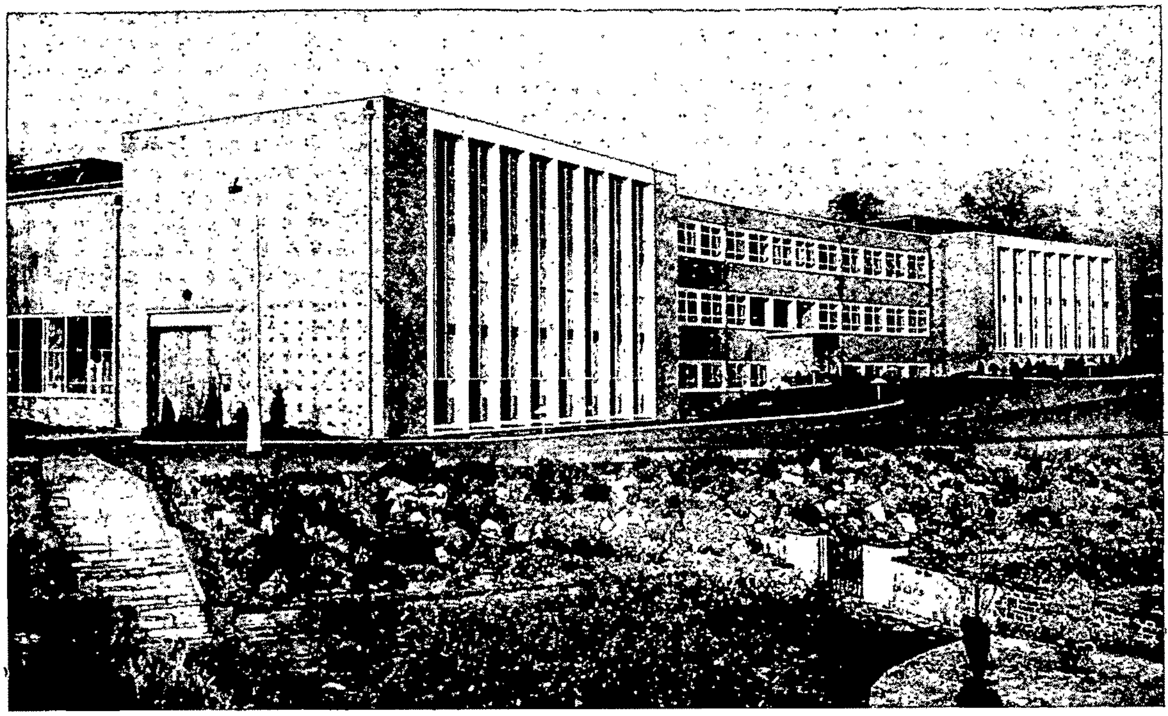

Fig. 1. The new Ferodo Research Laboratories at Chapel-en-le-Frith

this is warm filtered air which is led into each five-foot module, and afterwards extraction is by a fan system so designed that the air in each room is changed from four to five times every hour. The two outer wings are heated by unit heaters of the down-stream type fixed high in the roof and controlled by thermostats fixed at working level. Ventilation of these outer wings is by means of fresh-air ducts connected to the unit heaters and by extraction fans in the roof. In addition to gas, hot and cold water is provided, together with the usual electrical services. Steam is provided at 180 lb./sq. in. and at 40 lb./sq. in., and compressed air at 100 lb./sq. in. All services to the laboratories are housed in timber ducts that run along the walls from window-sill-level to floor-level. Services to island benches are accommodated beneath the timber and reinforced concrete floor.

The laboratories are lit by 80-watt fluorescent tubes in fittings on the ceilings, giving an average value of illumination of about 30 lumens per sq. ft. at desk-level. The Test House and Experimental Production Laboratory are lit by 250-watt mercury vapour lamps and 500-watt tungsten filament lamps which give an illumination of some 18 lumens per sq. ft.

The research and development programmes carried out in the new building are all directed towards the production of improved types of friction material for the automotive industry and for railways, aviation, mining and indeed every industry that employs moving machinery. Almost irrespective of the application, demands on friction materials are ever increasing both in number and intensity, and in the case of automotive brakes, for example, the peak energy dissipation per unit area has more than doubled within the past decade. Attention has not only to be given to the level of friction under varying conditions of pressure, speed, temperature and surface roughness, but also to durability, squeal, oil resistance, water resistance and many other such factors.

In order to be able to produce durable material with the required value of friction, research in the laboratories is carried out along many inter-related channels. Long-term work is carried out on the mechanism of friction and wear, and this involves the study of the bulk and surface properties of a wide range of different materials. Next, basic work of a medium-term nature follows on the friction materials themselves, and this has, as one of its objects, the further study of certain aspects of behaviour to which the long-term programme has directed attention. The third, last and most important link in the chain is the development of new friction materials to solve immediate problems, a process which, though continually eased by the ~~flow of knowledge~~ from the longer-term programmes, nevertheless ~~derives a~~ great deal from intuition and past experience. In parallel with this work on friction and wear, detailed researches are carried out on the properties of the more important raw materials. Asbestos is a particularly important material since, being a fibrous inorganic mineral, it is associated with three essential properties, namely, heat resistance, strength and flexibility. Studies on this mineral are being carried out by means of X-ray diffraction, electron microscopy and other techniques, and the structure of chrysotile and one of the amphiboles, namely, Bolivian crocidolite, has been elucidated. The investigations are run parallel with work on other properties of asbestos in order to obtain the clearest understanding of its many important characteristics. Investigations are also made of natural oils and resins by means of infra-red spectroscopy and liquid and gas chromatography, not only with the object of seeking a correlation between their properties and the friction and wear of the final product, but also to ensure that when complex mixes are involved, the components can be identified so that the activity of the oils can be maintained constant by a suitable system of blending. Mechanical investigations are used to examine the behaviour of the many different types of brakes and to record the conditions to which they are subjected in service. Surface temperature is one of the many important variables, and both its measurement and calculation are of vital importance.

The Test House contains test dynamometers of the inertia type for examining experimental materials under conditions that can be encountered in service. The machines are, in the main, automatic in operation and are self-recording, and permit a much closer control and therefore a better opportunity for studying the various factors affecting behaviour. The larger machines are designed to fit the types of brakes used on aircraft, heavy transport, railways and industrial brakes, while on the smaller machines provision is made to fit brakes varying from automotive to bicycle. The workshop adjoining the Test House is fully equipped to make all but the large parts of the various test machines, and the laboratories situated on a second floor over the workshop and test car garage are concerned with the design and construction of the various servo and other devices needed for the operation and control of the machines. Towards the end of the wing is a test car garage which houses a fleet of test vehicles, including motorcycles, large and small saloon cars, high-performance sports cars, lorries and buses. The vehicles are all fitted with instruments of various types which, in effect, make them mobile laboratories.

Although the laboratories stand adjacent to the factory, it was considered essential for them to be self-contained, and to this end the pilot-plant laboratory is equipped with all the production plant and finishing apparatus required to make prototype materials. Such provision not only enables development staff to plan their work more easily, but also frees production plant in the factory from costly interruptions. One section of this wing is allocated to the Production Plant Development Section, which carries out all the proving trials that may be necessary on new plant of a novel design. This design section works not only in close co-operation with the pilot plant section, but also with those chemists and physicists who are concerned with ideas still only in their embryonic stage.

Even this brief description of the laboratories should serve to show that the study of friction and the manufacture of friction materials involves contributions from chemists, engineers, metallurgists, mathematicians, statisticians, physicists and physical chemists. Indeed, the added interest gained from co-operating with so many different disciplines serves to render a fascinating study exhilarating.

The architects for the new Ferodo Research Laboratories were Messrs. Ashworth and Fletcher; the quantity surveyors Messrs. Worrell and Kelly; and the consulting engineers Messrs. R. W. Gregory and Partners.

THE SCIENCE MASTERS' ASSOCIATION

ANNUAL MEETING

THE annual meeting of the Science Masters' Association was held in University College and Queen Elizabeth College, London, during December 30–January 2, and was attended by a thousand members and many guests; this number included members from Canada, India, Pakistan, South and West Africa, and the United States. Among them was Prof. R. W. Lefler, of Purdue University, Indiana, who is at present acting as adviser in physics to the Nationalist University in Formosa.

The meeting began with the presidential address by Sir Lawrence Bragg, who outlined the past history and present policy of the Royal Institution. The second evening was occupied by a lecture by Dr. H. Lister on the recent Trans-Antarctic Expedition; this was notable for the splendid coloured slides.

The programme of morning lectures by members of the staff of University College, together with guest lecturers from Harwell, the Brunel College of Technology, the London Institute of Education, and Woodberry Down School, London, has already been given in *Nature* (December 6, p. 1554). One of these, that by Mr. H. G. Conway, of Short Brothers and Harland, Belfast, on "New Engineering Problems in Aeronautics", was attended by Air Marshal Sir Owen Jones, president of the Institution of Mechanical Engineers, and other members of the Institution.

The Manufacturers' and Publishers' Exhibitions, held in University College, were larger than ever before, with the result that the exhibition of apparatus and other items brought by members had to be housed in Queen Elizabeth College. Among these exhibits was an intensely interesting historic one, namely, Faraday's bible, shown by Mr. E. H. Duckworth, of Cheltenham; this contained Faraday's autograph and his original marking of important texts.

The Science and Religion Group was addressed by the Rev. Aubrey Vine, general secretary of the Free Church Federal Council.

An innovation was the organization, at the suggestion of Mr. D. G. Chisman, education officer of the Royal Institute of Chemistry, of evening receptions by that Institute and by the Institutes of Physics and of Biology. These were much appreciated by members, as was shown by the fact that applications to attend far exceeded the available accommodation. The afternoons were occupied by visits to university departments and to factories in or near London; for other members there were exhibitions of scientific films.

At the business meeting of the Association Mr. D. G. James, vice-chancellor of the University of Southampton, was elected president for the ensuing year: Dr. H. F. Boulind, of the University of Cambridge Department of Education, was elected chairman, and Mr. H. Lockett, of Taunton's School, Southampton, became the new annual meeting secretary. It was announced that a summer meeting would be held, during July 28–31, in the Durham Colleges of the University of Durham. The next annual meeting will be in the University of Southampton, during December 29–January 1, 1960.

The second half of the business meeting was occupied with the discussion of a resolution, moved by Mr. D. N. Underwood and Mr. E. Chanter, which read: "that this meeting disapproves of the continued teaching of General Science as a substitute for the separate sciences". The chairman, Mr. Charles Holt, said that it was somewhat unusual for resolutions of this kind to be brought forward at the business meeting, but that the General Committee had decided that a useful purpose would be served if it were discussed. The Committee had always tried to avoid "coming down heavily on any particular side in science, because it took the view that members were so differently situated that they might find they had different needs at different stages of the work".

Mr. Underwood said the decision to move the resolution had been taken during the annual meeting last year at Leeds; concern on the subject had also been shown in articles in the *School Science Review* and in many letters and comments which the proposers had received in favour of the resolution. They were concerned chiefly with the effect of the teaching of general science on potential scientists, and not so much with that on the weaker grammar school and modern school pupil. It was a fallacy to think that physics, chemistry, and biology could be lumped together as general science; they were different disciplines and should be taught by experts. General science meant reduced time for science and provided little opportunity for practical work.

Mr. Chanter, in seconding the motion, said that in general science "one had to go quickly from one thing to another and the pupil never really got his teeth into anything". He did not believe that was real education at all.

The discussion was opened by a member who said that the sciences were humanities, and that the most human things about them were the barriers between them; the thing about chemistry which made it not physics was one of the most charming things.

Mr. J. A. Storer suggested an amendment, which was supported by Mr. D. Lewis (Bristol). This was later withdrawn after Mr. R. H. Dyball (City of London School) had proposed the altered wording "that this meeting disapproves of the continued teaching of general science on an inadequate time allowance". Mr. H. P. Ramage (Gresham's School, Holt) supported Mr. Dyball, and said that if physics, chemistry, and biology, with some geology and astronomy, were studied separately, it was still general science in the Association's meaning of the term. He would like to see enough time given to teach all these subjects up to Advanced (*A*) level; but the original resolution, if carried, would be misquoted and give a very wrong impression. After further discussion, the amendment proposed by Mr. Dyball was carried by an overwhelming majority.

The second discussion was on the Association's policy statement, "Science and Education", which has been widely distributed in educational circles. This was introduced by the chairman-elect, Dr. H. F. Boulind, who said that the main reason for the statement was "dissatisfaction with the present state of science teaching; the country is not producing the scientists, technicians, and technologists required". Secondly, it is science which is shaping the modern world, and some reasonable standard of scientific understanding is essential for everyone. The statement was produced by a sub-committee of two physicists, two chemists, and two biologists, and had been almost unanimously approved by the General Committee. It had been discussed with the Minister of Education and with Under-Secretaries, with the Central Advisory Committee, and with the Secondary School Examinations Committee; later work had been undertaken by specialist panels. Among the recommendations were the following: "that all pupils should follow an adequate course in science up to the end of the fifth-form year"; that "science should be studied by all pupils in the sixth form", and that "subject specialization should be retained in the sixth form but that *A* level syllabuses should be reduced in factual content".

In the discussion, a member said the problem should be considered from the point of view of the non-scientist; many important subjects are left out at Ordinary (*O*) level, so that pupils leaving at the age of 16 never touch them. Several members commented that the examining boards are favourable to a reduction in the factual content of examinations. Mr. W. H. Dovell (Lancing) thought that there are too many topics of interest only to the specialist in the *O* level course. He also asked for Dr. Boulind's views on the number of teaching periods a week. Dr. Boulind, in reply, said that nine periods a week should be adequate up to *O* level. Many members dissented at once. Mr. G. A. Lees (Collyer's School, Horsham) said that the policy statement was a very good effort, but that practical details as to time allowances were much more important. Further discussion centred on the question whether junior school science teaching should all be in the hands of one teacher or in those of specialists; on the influence which the Association might exert in introducing science into the common entrance examination for public schools; and on the effect of the statement on science teaching in modern schools and comprehensive schools. The chairman, in closing the discussion, mentioned that Dr. Boulind had been mainly responsible for the policy statement.

MANAGEMENT THEORY

THE third booklet in the "Problems of Progress in Industry" issued by the Department of Industrial and Scientific Research (Management and Technology. By Joan Woodward. Pp. 40. London: H.M. Stationery Office, 1958. 2*s*. 6*d*. net) describes a survey of the management organization of a hundred firms in south Essex. The survey attempted to discover whether the principles of organization laid down by an expanding body of management theory correlate with business success when put into practice. The survey was made between 1953 and 1957 by the Human Relations Research Unit of the South-East Essex Technical College, and after a basic survey of 91 per cent of manufacturing firms in south Essex with more than a hundred employees, twenty firms were studied more fully and detailed case-studies made of three firms in which production systems were mixed or changing. A full report of the research with a discussion of its theoretical implications is projected shortly under the title "Management

Organization: Theory and Practice". Among the large-batch and mass-production firms a relation was observed between conformity with the 'rules' of management and business success, and, within this limited range of production systems, observance of these 'rules' appears to increase administrative efficiency. Elsewhere, however, it appears that new 'rules' are needed and an alternative kind of organizational structure might be more appropriate. This does not invalidate management theory, which contains important and valuable information and ideas, but its limitations must be recognized and its principles subjected to critical analysis. Broadly, the survey brings out the way in which management organization varies according to the technical demands of the manufacturing process. The character of the basic functions of management, their chronological sequence, their integration and their relative importance to the success and survival of the business, all depend on the system of techniques in the particular firm, and they differ mainly between unit, mass and process production, all of which have different priorities.

Accordingly, a 'cause and effect' relation can be traced between a system of production and its organizational pattern, and, as a result, the probable organizational requirements predicted. The booklet emphasizes the danger in the tendency to teach the principles of administration as if they were scientific laws, when they are really little more than administrative expedients. Management studies can, so far, identify symptoms and remedies, but many more descriptive accounts, like that given in this booklet, of the circumstances in which different administrative expedients have proved successful are required to supplant traditional teaching. It is also concluded that technical changes not associated with changes in either objectives or the production system are unlikely to create much disturbance in the organizational pattern. Where, however, such changes are likely to create new 'situational demands', these could be foreseen by a systematic analysis of the new technology.

HUMAN RELATIONS IN INDUSTRY

IN its final report*, the Joint Committee on Human Relations in Industry, 1954–57, reviewing research projects approved since its first report, records that a practical inquiry into the effects of work study on human relations and organization at every level in the firm is well advanced, and further support was recommended for a team from the University of Manchester to continue to work on a large scale for three years on social factors affecting norms of production in British factories. An investigation into incentives for management had to be abandoned because suitable staff could not be found, but the National Institute of Industrial Psychology has been asked to undertake case-studies of the way in which individual firms have tackled the problem of foremanship.

Research in the field of industrial communication has been extended to cover the communication of technical information to firms from outside sources, and the inquiry conducted by the Oxford Institute of Statistics into factors affecting productivity has been extended to social factors in seeking for an explanation—psychological and social, as well as economic—of differences in productivity between and within the firms studied. Research into the community aspects of technological change in South Wales has centred around the exceptionally modern and highly mechanized Margam steel plant and, at Cardiff, on the impact made on the structure and procedure of the trades unions by the new steel plant.

The Acton Society Trust is making a case-study of the introduction of a management-development programme, and a study of educational provision and the needs of industry by the Tavistock Institute of Human Relations is also being supported. Work at the London School of Economics on the employment of women in industry was extended for two years, and some exploratory work was undertaken at the University of Edinburgh into the employment of older workers in industry.

Projects sponsored by the Joint Committee on Individual Efficiency in Industry fall into four groups. Those concerned with factors affecting equipment design and working conditions include two studies, by the Medical Research Council's Applied Psychology Research Unit at Cambridge, of manual controls of machine tools and of visual fatigue. The former greatly increased the speed of machine-working and reduced the number of errors and learning-time. Other studies were concerned with the design and layout of control points in steelworks, with special reference to crane-cabs, with machine controls in relation to equipment used in the boot and shoe industry and with the response to work in high temperatures in relation to age. Projects concerned with industrial engineering techniques embrace those of the nature and acquisition of industrial skills by the Department of Engineering Production at the University of Birmingham and of work-study rating, rest and fatigue allowances by the Department of Aircraft Economics at the College of Aeronautics, Cranfield.

Studies of problems of training include those by the National Institute of Industrial Psychology of methods of training in industrial skills; of conditions influencing the rate of learning of paced and unpaced motor tasks by the University of Oxford Institute of Experimental Psychology; of the methods used by the best operatives and their application to the training and re-training of operatives by the British Boot, Shoe and Allied Trades Research Association; and of reading efficiency by the Department of Commerce and Professional Studies at the North-Western Polytechnic, London.

Among the group of miscellaneous projects may be mentioned one on the effect of knowledge of results on production made by the Medical Research Council's Applied Psychology Research Unit; an investigation of indices commonly regarded as indicating the adjustment of the individual to his job; and a study of automation in relation to skill and the design of machines by the Department of Psychology, University of Cambridge.

A CASE OF HUMAN INTERSEXUALITY HAVING A POSSIBLE XXY SEX-DETERMINING MECHANISM

By PATRICIA A. JACOBS and DR. J. A. STRONG

Medical Research Council Group for Research on the General Effects of Radiation and Department for Endocrine and Metabolic Diseases, Western General Hospital and University of Edinburgh

RECENT improvements in techniques for the examination of human somatic chromosomes have made possible the study of the chromosome complement of human intersexes; consequently, it is now practicable to investigate the relationship in these cases between sex as determined by direct chromosome study, and sex as inferred from the study of 'nuclear sex chromatin' of the type described by Barr and Bertram[1]. This report is concerned with one of a series of patients with gonadal dysgenesis who are under investigation, and the particular feature of interest is the occurrence of 47 somatic chromosomes in contrast with the normal number of 46 in man.

In recent years the diploid chromosome number of 46 has been recorded in a large number of instances. In addition to the 60 cases cited in a previous publication[2] we have recorded a diploid number of 46 in bone marrow preparations from a further 40 European subjects. Kodani, on the other hand, has recently published results of counts made on testicular material from 36 Japanese and 8 American white males[3,4]. He claims that in 16 Japanese and 1 American there was a diploid number of 48; in 2 Japanese a diploid number of 47, and that in the remaining 13 Japanese and 7 whites the number was 46. He suggests that 46 is the basic diploid chromosome number for man, but in some instances there are additional "supernumerary chromosomes". The occurrence of this type of supernumerary chromosome, however, has not been reported previously among the vertebrates and awaits confirmation by other workers.

Our patient, an apparent male aged twenty-four, was presented as a case of gonadal dysgenesis with gynæcomastia and small testes associated with poor facial hair-growth and a high-pitched voice. Biopsy examination of testicular tissue showed the seminiferous tubules to be extremely hyalinized and atrophic, and also an apparent increase in the number of interstitial cells. Chromosome studies were attempted on part of this material, but no spermatogonial mitotic or meiotic divisions were seen. Smears made from both the buccal mucosa and the blood were examined by Dr. B. Lennox of the Department of Pathology, Western Infirmary, Glasgow, and found to demonstrate typical female morphology with regard to their nuclear sex chromatin.

Material obtained by sternal marrow puncture was used for investigating the somatic chromosomes. The technique used for culturing the material in the presence of colchicine and for making squash preparations has already been described[2].

The chromosomes were counted in 44 cells in metaphase and the results are shown in Table 1.

The majority of the cells contained 47 chromosomes, and in all those cells where the chromosomes were well fixed and spread, the count was undoubtedly 47 (Fig. 1). The apparent variation is in all probability due to technical errors. Fragments of cells containing chromosomes may become lost during the squashing process so that counts lower than the diploid number are obtained; and occasionally chromosomes split at the centromere and individual chromatids may be counted as chromosomes, giving a count higher than the diploid number[2].

Table 1

Chromosome No.	45	46	47	48	49
No. of cells	2	7	29	5	1

A study of the chromosome morphology in 8 cells of a suitably high standard showed that each of these had a normal male complement with the Y chromosome present, but that there was also an extra chromosome having a sub-median centromere occurring in the medium size range. In the normal male there are 15 chromosomes in this range, and in the female 16, all having sub-terminal or sub-median centromeres[2]. Owing to the slight variations in their size and morphology these chromosomes have proved difficult to pair, and it is in this category that the X chromosome is to be found.

There are strong grounds, both observational and genetic[5,6], for believing that human beings with chromatin-positive nuclei are genetic females having two X chromosomes. The fact that this patient is chromatin-positive and has an additional chromosome within the same size range as the X, as well as an apparently normal Y, makes it seem likely that he has the genetic constitution XXY. The possibility cannot be excluded, however, that the additional chromosome is an autosome carrying feminizing genes.

The presence of the extra chromosome might have been due to one or other of the parents having 47 chromosomes, and, therefore, chromosome studies were made on marrow specimens from both parents. Both were found to have a diploid number of 46 (Table 2), and analysis of cells of suitable quality showed the morphology of the chromosomes to be normal.

The occurrence of the extra chromosome therefore may be due to non-disjunction at either mitosis or meiosis during gametogenesis in one or other parent. Alternatively, it may be due to non-disjunction

Fig. 1. Metaphase plate showing 47 chromosomes

Table 2

Father	Chromosome No.	44	45	46	47	48	49
32 cells counted	No. of cells	2	3	26	–	–	1
Mother	Chromosome No.	44	45	46	47	48	49
39 cells counted	No. of cells	1	3	33	2	—	–

occurring during the patient's very early embryological development, in which case there is a possibility that the patient may be a mosaic. Unfortunately, it is not possible with the techniques at present available to examine the chromosomes of tissues arising from different germ layers of the embryo.

We would like to thank Dr. B. Lennox of the Department of Pathology, Western Infirmary, Glasgow, for checking the nuclear sex of the preparations of buccal mucosa and blood and Miss M. Brunton for technical assistance.

A further report of this and other cases will follow.

DISTRIBUTION OF NEWLY SYNTHESIZED DEOXYRIBONUCLEIC ACID IN DIVIDING CHROMOSOMES

By PHILIP S. WOODS and MARIE U. SCHAIRER
Biology Department, Brookhaven National Laboratory, Upton, Long Island, New York

FROM autoradiographic studies with tritiated thymidine, newly synthesized deoxyribonucleic acid was shown to be equally distributed between both daughter chromosomes at anaphase by Taylor, Woods and Hughes[1] (Fig. 1*A* and *B*). When the labelled chromosomes were allowed to duplicate a second time in a medium containing no radioactive tracer, the isotope appeared in only one daughter chromosome of each sister pair (Fig. 1*C*). These findings differed markedly from the earlier conclusions of Plaut and Mazia[2], whose interpretations were based on the analysis of deoxyribonucleic acid labelled with carbon-14 in whole sets of daughter chromosomes in anaphase and telophase. Since they observed significant differences in the amount of label between the two daughter nuclei, they concluded that individual chromosomes were also labelled unequally. Recently, La Cour and Pelc[3] reported that unequal labelling could occur as a result of treatment with colchicine. Since in the experiment of Taylor *et al.* colchicine was present during the second synthesis and absent during the first, they suggested that colchicine may produce the unequal label.

In order to clarify the situation, the experiments of La Cour and Pelc were repeated. Since critical quantitative data were lacking in their experiments, information in the form of grain counts over a number of daughter chromosome pairs were collected and the chi-square test applied to determine any significant deviations between daughter halves.

The experiment went as follows: two seedlings of *Vicia faba* were grown in separate nutrient solutions containing tritiated thymidine (1·4 μgm./ml., 2·0 μc./ml.). One solution contained in addition 0·03 per cent colchicine. After 8 hr. the seedling which was treated with thymidine labelled with tritium alone was removed and placed in a non-labelled solution containing 0·03 per cent colchicine. After 6 additional hours two roots of this seedling were fixed, stained by the Feulgen squash procedure, and covered with autoradiographic stripping film. The other

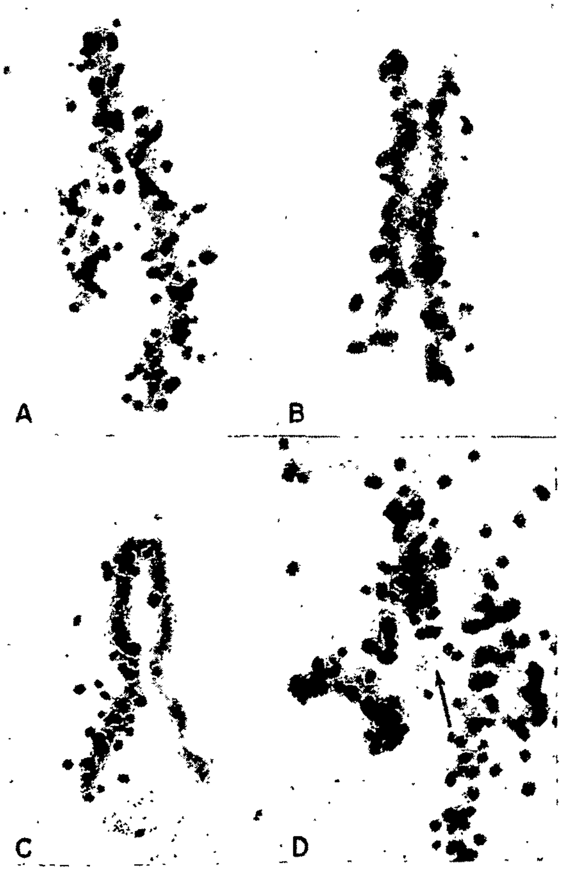

Fig. 1. *A*, autoradiograph of chromosome number 9 of second root of Table 2, colchicine present during synthesis; *B*, autoradiograph of chromosome number 4 of second root of Table 1, colchicine absent during synthesis; *C*, autoradiograph of chromosome from root treated with tritiated thymidine for 8 hr. followed by colchicine solution without tritiated thymidine for 30 hr.; *D*, autoradiograph of chromosomes from lightly squashed root from same seedling as that used in *B*

seedling was grown for a total of 12 hr. in the labelled thymidine–colchicine solution, and then two roots were fixed and processed identically with those of the first seedling. Definite criteria were followed for obtaining the grain counts. Since Fitzgerald *et al.*[4] have shown that 90 per cent of the beta-particles emitted by tritium are absorbed by filters (corrected to unit density) with a thickness of only 1·2μ, labelled material would not be expected to register fully unless in direct contact with the photographic emulsion. Therefore, we have scored only those chromosomes that were seen by the phase-contrast microscope to be in direct contact with the emulsion. All other chromosomes such as those with varying thicknesses of cytoplasm or cell wall lying above were rejected. The first 25 chromosomes encountered where the criteria were fulfilled were counted for each of the four roots. Thus, 50 chromosomes were scored from each of two roots where colchicine was either present or absent during the period of synthesis of deoxyribonucleic acid.

Tables 1 and 2 show the results of these experiments. The fourth column of each table shows the mean or expected count for the left and right chromatid of each chromosome if equal labelling were to occur. The last column of each table shows the values of chi-square for each chromatid pair. It is clear from the high probability values that the observed grain count values do not differ significantly from the expected values of the 1 : 1 hypothesis. Apparently each daughter chromosome of a pair contains the same amount of new deoxyribonucleic acid. Also, there appears to be no difference between the two treatments. The presence or absence of colchicine during synthesis has no effect on the distribution of the labelled material. Fig. 1*A* and *B* illustrates two chromosomes that were counted for each treatment.

Explanation of the findings of La Cour and Pelc[3] in the light of the present results should be considered. In our opinion, differential absorbance of tritium beta-particles by varying thicknesses of cytoplasm and other cellular components has not been sufficiently considered by these workers. It is probable that a chromosome labelled with tritium would not produce a satisfactory autoradiograph if it were separated from the emulsion during exposure by a layer of dry cytoplasm only a few microns thick.

It is clear that unless the chromosomes are heavily squashed so that the thickness of the absorbing layer is reduced to a minimum or is at least constant, inconsistent results would be expected. Fig. 1*D* shows a preparation in which one chromosome (arrow) of a group was farther from the emulsion than the others and in which the absorbing layer was thicker.

This investigation was carried out at Brookhaven National Laboratory under the auspices of the U.S. Atomic Energy Commission.

SEPARATION AND ANALYSIS OF SCALE-RICH MATERIAL FROM WOOL

By Dr. J. H. BRADBURY

Wool Textile Research Laboratories, Commonwealth Scientific and
Industrial Research Organization, Geelong,
Australia

THE scales of animal fibres can be removed by physical methods such as abrasion[1-3], by enzymic methods[4], and by chemical methods[5-8]. The disadvantage of the chemical and enzymic methods is that it is impossible to estimate the degree of degradation of the scales which has occurred during the treatment. The abrasion technique has not been used for producing scales for analysis but rather to obtain descaled fibres for analysis[2] and dyeing experiments[3]. In this communication an abrasion technique is used to produce 0·5-mgm. amounts of scale-rich material which are quantitatively analysed for amino-acids by Levy's method[9].

The glass descaler is shown in Fig. 1. The central rod *A* comes to a chisel edge at *B*, which is fire-polished and has a cut made across it with a sharp glass-knife. This serves as an abrasive groove for the wool fibre *C*, which is held by tweezers and threaded through the holes *D* at either end of the descaler. When the fibre is rubbed once back and forth along the groove small particles are abraded and collect on the sides of the descaler. To ascertain the depth of abrasion of Lincoln 36's and Corriedale 46's fibres they were ring-dyed with 0·01 per cent Cibalan Bordeaux 3*BL* in 0·1 per cent glacial acetic acid at 80° C. for 1 hr., cross-sectioned with a Hardy microtome and the average depth of dyeing measured over 100 cross-sections. This amounted to 3·1 and 2·9 per cent of the diameter for Lincoln 36's and Corriedale 46's, respectively. Before use, each descaler was tested with the appropriate ring-dyed fibres and the scale material examined under the microscope. In every case it consisted of small, coloured pieces, showing that it originated from the outside layers of the fibre. A further check was made by calculating the average dimensions of the material abraded, from a knowledge of the percentage by weight removed from one side of the fibre, which is assumed to be circular in cross-section. When 0·50 per cent by weight of the fibre is abraded the calculated average depth of abrasion at the deepest point amounts to 2·0 per cent of the diameter. Since the thickness of the scales as determined by microscopy[10] is about 1·7 per cent of the diameter, the abraded material is very largely, but not entirely, scales.

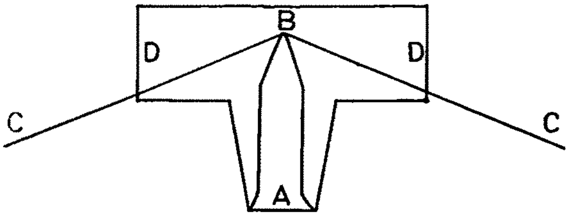

Fig. 1. Glass descaler, distance $DD \simeq 3$ cm., $AB \simeq 2$ cm.

After such preliminary testing each descaler was carefully cleaned, dried and allowed to come to constant weight at 65 per cent relative humidity and 20° C. After about 0·5 mgm. of scale material had collected from the abrasion of 200–400 fibres (cleaned as described previously[11]) the descaler was again weighed to constant weight ($\pm 5 \times 10^{-3}$ mgm.) and placed inside a large, carefully cleaned 'Pyrex' test-tube. Twice glass-distilled 6 *M* hydrochloric acid (2 ml.) was added, the tube sealed under vacuum and heated at 105° C. for 16 hr. The hydrolysate was dinitrophenylated by Sanger's method[12] and the dinitrophenyl-amino-acids separated and estimated by a modification of the method of Levy[9] which will be described elsewhere. Similar quadruplicate analyses of whole fibres were made for the three different samples of wool recorded in Table 1.

It is clear that the scales are rich in proline and poor in aspartic acid and glutamic acid in all three wools examined. However, substantial differences

Table 1. Percentage Deviations of Amino-acid Content of Scale-rich Material from that of Whole Fibre which are significant at the 1 per cent Probability Level unless otherwise stated

Amino-acid	Lincoln 36's (virgin wool, tips removed)	Lincoln 36's (obtained in top form)	Corriedale 46's (virgin wool, tips removed)
Asp Glu	− 27·5*	− 14·2† − 13·0	− 24·1 − 22·7*
Pro	+ 33·0	+ 20·6	+ 27·3*
Cys	—	+ 21·8	—
Gly	+ 38·7	—	—

* Significant at the 5 per cent probability level.

† $P = 0{\cdot}068$ in this case due to poor separation of DNP-Asp from DNP-Glu in some of the experiments.

between types may be expected since the scales are rich in glycine in Lincoln 36's virgin wool and rich in cystine in Lincoln 36's top. Scale material produced by various degradative chemical methods is reported to contain more cystine and less tyrosine than the whole fibre[5-8]. The differences between such results and those given here are due to the different methods of separating the scale material and possible variations in composition between various samples of wool and between the three histological components of the scales[13].

It is perhaps significant that the scales which are known to be amorphous[5,14,15] have a higher proline content than the fibrous cortex[16]. However, the large differences in chemical reactivity between cuticle and cortex are probably due more to differences at the molecular and higher levels of organization than to differences in chemical composition.

I thank Dr. M. Lipson for suggesting this line of work, Mr. J. Delmenico for advice on dyeing and microscopy, and various colleagues for helpful discussions. Mr. H. Groll has rendered valuable technical assistance.

THICKNESS OF THE EARTH'S CRUST IN ANTARCTICA

By F. F. EVISON, C. E. INGHAM and R. H. ORR

Department of Scientific and Industrial Research, New Zealand

ANTARCTICA has always been regarded as a continent by virtue of its size, but recent soundings have revealed that the ice-cap extends well below sea-level in many places, perhaps by as much as 2,000 metres. Whether the surface of the rock in such areas would remain submerged if the ice were to melt is largely a question of the ensuing isostatic adjustment. A more direct means of verifying the continental status of Antarctica is to determine the thickness of its crust, for all the established continents have a crustal thickness of 30–40 km. or more, in contrast to thicknesses of 5–15 km. in oceanic regions. The continental type of crust may be readily distinguished from the oceanic type by a study of the dispersion of earthquake waves travelling in the crustal layers, provided that suitably located shocks and seismograph stations are available. Dispersive waves from an earthquake of September 9, 1957, with epicentre (Fig. 1) in the south-east Indian Ocean (47$\frac{3}{4}$° S., 101° E.), were recorded at Scott Base and Hallett Station after traversing Antarctica for approximately 2,000 km., that is, about half the total path. An analysis of these waves has shown that the thickness of the crust in eastern Antarctica is about 35 km.; thus the existence of a true antarctic continent is confirmed.

The analysis was facilitated by a study of records of the same earthquake at Mirny, which indicated further that the thickness of the crust beneath the south-east Indian Ocean is about 9 km. The stations from which these results have been obtained were participating in the antarctic programme for the International Geophysical Year. Columbia University seismographs were used at Hallett Station (U.S.A.–N.Z.), Benioff seismographs at Scott Base (N.Z.) and Kirnos seismographs at Mirny (U.S.S.R.).

The wave-paths, shown in Fig. 1, were peculiarly favourable for the present study. The waves arrived well dispersed at Scott Base and Hallett Station, and the dispersion was influenced to a suitable extent by the segment of the path across Antarctica. Close similarity could be assumed between the oceanic structure affecting these paths and that for the path to Mirny. Although all the paths were rather shorter than would ordinarily suffice to prevent confusion among different types of wave, the directions of arrival were nearly ideal. Thus Rayleigh waves were

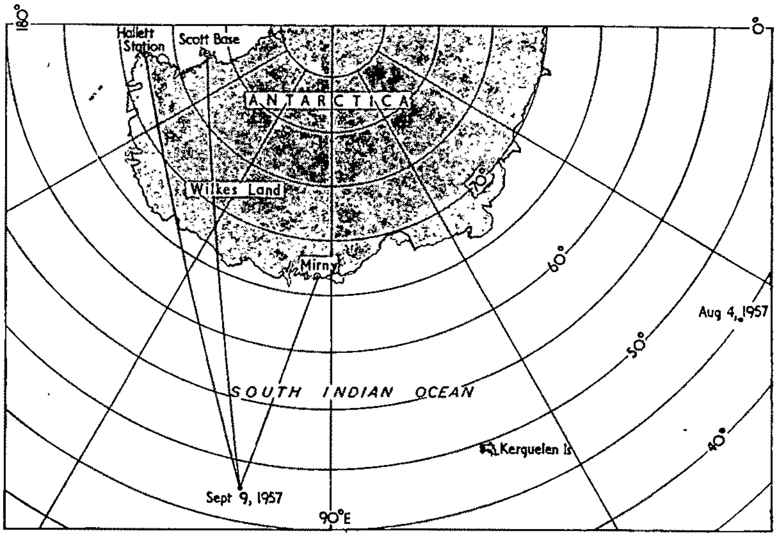

Fig. 1. Wave paths from earthquake epicentre to seismograph stations. (Polar stereographic projection)

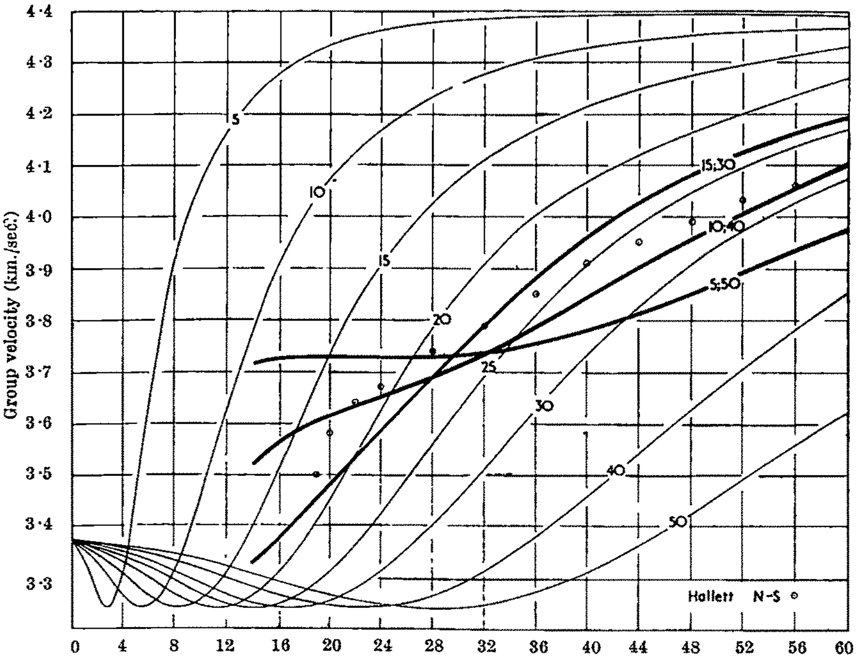

Fig. 2. Love wave dispersion. Theoretical curves are shown for crustal thicknesses from 5 km. to 50 km., with the following seismic constants. Shear velocities: crust, 3·47 km./sec.; mantle, 4·50 km./sec. Density ratio (mantle/crust), 1·283. The heavy curves are for composite paths, with one-half of the path at each of the thicknesses shown

clearly selected by instruments recording the east–west component at Scott Base and Hallett Station, and by the north–south instrument at Mirny, as well as by all the vertical instruments. Likewise, the Love wave was well recorded by the north–south instrument at Hallett Station; but the constants of the north–south instrument at Scott Base made it unsuitable for recording Love waves, and the path to Mirny was too short. The dispersion observations were analysed in the usual way[1], and interpreted by comparison with theoretical results. A three-layer model was adopted for the oceanic segment of the path, and a two-layer model for the land segment. The seismic velocities and densities of the crust and mantle respectively were assumed the same for Love and Rayleigh waves, and also for the oceanic and land segments.

The results for the Love wave recorded at Hallett Station are shown in Fig. 2. The family of theoretical curves was derived from parameters computed by Stoneley[2], each curve indicating the variation of group velocity with period for a particular crustal thickness. None of these curves approximates to the plotted observations, but a rather close fit is obtained by combining a pair of curves so as to allow for different thicknesses in the two segments of the path. With the segments equal in length, the composite group velocity for any period is the harmonic mean of the group velocities pertaining to each segment. Three such composite curves are shown in Fig. 2, from which it appears that the required crustal thicknesses are rather less than 40 km. for the antarctic segment and rather more than 10 km. for the oceanic segment.

The Rayleigh waves recorded at Scott Base, Hallett Station, and Mirny are analysed in Fig. 3 and provide an independent and rather more strongly supported solution. For an oceanic path the dispersion of Rayleigh waves differs from that of Love waves in being influenced by the liquid layer; thus two distinct families of curves are needed in considering a composite path. But the path to Mirny may be taken as purely oceanic, so in the present case a separate solution is obtained for the oceanic crust. A satisfactory fit to the Mirny observations was achieved by assuming a ratio of 2 : 1 between the crustal thickness and the depth of liquid, the actual values obtained being 9 km. and 4½ km. respectively. The latter value is consistent with the mean depth of water of 3·8 km. estimated from the bathymetric chart[3]; for studies of dispersion in the Pacific and Atlantic Oceans[4] have shown that the liquid layer usually includes unconsolidated bottom sediments to a

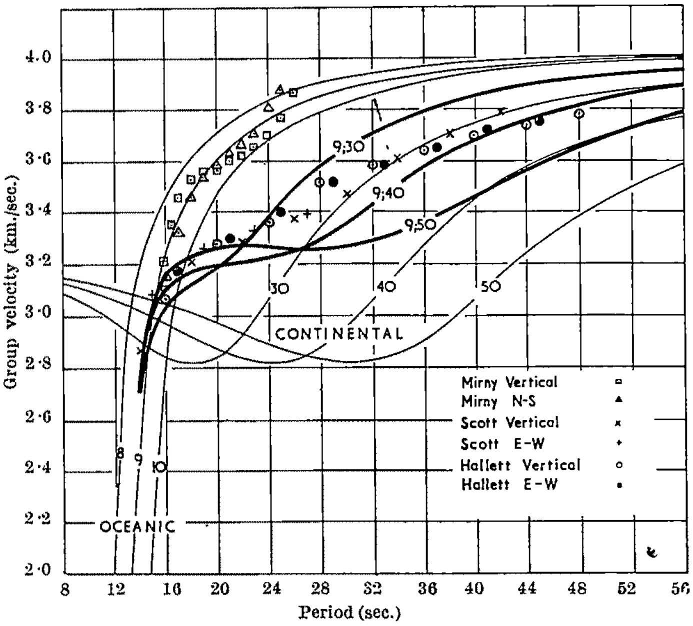

Fig. 3. Rayleigh wave dispersion. Theoretical oceanic curves are shown for crustal thicknesses of 8, 9 and 10 km., with depths of water equal to one-half the crustal thickness in each case. The continental curves are shown for crustal thicknesses of 30, 40 and 50 km. The following seismic constants were assumed, in addition to those of Fig. 2. Compressional velocities: water, 1·52 km./sec.; crust, 6·01 km./sec.; mantle, 7·79 km./sec. Density ratio (crust/water), 2·65. The heavy curves are for composite paths, with one-half of the path at each of the thicknesses shown

thickness of 0·5–1·0 km. From the composite curves in Fig. 3 it is concluded that the thickness of the crust of Antarctica is about 35 km.

The estimated values of crustal thickness, although derived from a single earthquake, receive support from the consistency that has appeared in the results for Love waves and Rayleigh waves. The method does not offer a high degree of precision, however, because of the simple models that must be assumed in order to keep the labour of computation within reasonable limits. A preliminary analysis has been made for a second earthquake, which occurred on August 4, 1957, in the south-west Indian Ocean (45° S., 35° E.) (see Fig. 1); this also indicates a thickness of about 35 km. for the crust of Antarctica. Analyses are in hand extending this study to other sectors of Antarctica, and the results will be published in full elsewhere.

This work has been made possible by the efforts of the New Zealand International Geophysical Year antarctic party under the supervision of Dr. T. Hatherton, chief scientist. We also desire to acknowledge the courtesy of the Institute of Physics of the Earth, Moscow, in providing a copy of the Mirny records.

RESPONSES OF SEEDLINGS TO EXTRACTS OF SOYBEAN NODULES BEARING SELECTED STRAINS OF *RHIZOBIUM JAPONICUM*

By HERBERT W. JOHNSON, URA M. MEANS and FRANCIS E. CLARK
Agricultural Research Service, U.S. Department of Agriculture, Beltsville, Maryland

ERDMAN *et al.*[1] reported that some varieties of soybeans (*Glycine max* (L.) Merrill) develop chlorosis when nodulated with selected strains of *Rhizobium japonicum*, whereas other varieties do not. Johnson *et al.*[2] obtained differential responses of soybean genotypes to various environmental conditions and succeeded in producing chlorosis in varieties previously considered resistant by varying nutrient and substrate conditions. Johnson and Clark[3] used approach grafts between resistant and susceptible varieties to demonstrate that resistance or susceptibility is conditioned by the rootstock. They also found that chlorosis appeared in a difficultly nodulating genotype only after root nodules developed. They concluded that the substance causing chlorosis originated in the nodule.

In previous work the effects of treatments on chlorosis were evaluated in terms of the responses of the soybean genotypes cultured as host plants. An observed effect could have been due to the response of the soybean genotype to the treatment, a response of the bacterial genotype, or both. The experimental techniques employed did not permit separation of these effects. Objectives of the present work were to develop a technique for evaluating the production of the chlorosis-inducing substance independently of the symptoms of the top portions of the nodule-bearing plants and to test the effects of the substance on other plant species.

Nodules from chlorotic soybean plants inoculated with chlorosis-inducing *R. japonicum* strain 76 and from normal plants inoculated with strain 31 were used as source material. Host plants were of the Lee variety. It should be noted, however, that similar research with other bacterial strains and soybean varieties has demonstrated that results to be reported are not peculiar to the source materials of this study. In preliminary work, weighed amounts of fresh nodules were macerated in a crucible in measured quantities of water and the suspension filtered. Such filtrates supported luxuriant growth of micro-organisms, and their chlorosis-inducing properties deteriorated rapidly. Filtrates autoclaved at 120° C. for 20 min. remained fully effective in inducing chlorosis, and once autoclaved they could be stored for several months at room temperature without measurable deterioration in activity. Sterile and initially highly active extracts deliberately contaminated with small quantities of soil lost their chlorosis-inducing activity during the first week after contamination. Extracts prepared from nodules frozen for as long as six months or from nodules dried in the greenhouse for as long as one month were not measurably different in activity from those prepared from fresh nodules.

For the tests reported here, nodule extract was made by blending fresh nodules in water in a Waring-type blendor in the proportion of 1 gm. of fresh nodules to 25 ml. of water. This stock extract was autoclaved at 120° C. for 20 min. and stored aseptically until used.

In testing for seedling responses, seeds were surface-sterilized or treated with 'Spergon', germinated in sand, and, at emergence, seedlings were transferred to vials containing the test solution. The capacity of the vials varied from 4 to 10 ml. depending on the size of the seedlings involved. These small reservoirs suffered depletion because of evaporation and consumptive intake of water. Additional test solution was added to them for replenishing the supply when necessary.

Chlorosis of the unifoliate and the first trifoliate leaves of soybean seedlings was scored from 1 (slight) to 4 (severe). Plants of other species were scored on the same scale and at comparable stages of development. Species tested are listed in Table 1.

Extracts from nodules of normal green soybean plants nodulated with strain 31 were included as checks in all experiments. None of the many seedlings grown in them developed chlorosis. To facilitate presentation of results, nodules or extracts from normal plants are referred to as the *N* type and those from chlorotic plants nodulated with strain 76 as the *C* type. Concentrations of the extracts are stated as fractions, indicating 1 gm. of fresh nodule/ml. of water.

Soybean seedling responses. Both *N* and *C* extracts more concentrated than 1/50 were toxic to all soybean seedlings grown in them, and little chlorosis developed. The toxic effects appeared to be due primarily to damage of the root system. Development of branch roots was inhibited, and the main root quickly developed a greyish-brown water-soaked appearance.

Growth was retarded in 1/50 extracts, but slight chlorosis of the unifoliate leaves and moderate chlorosis of the first trifoliate leaves developed on seedlings grown in *C* extract. Seedlings of the highly susceptible Lee variety and those of the slightly susceptible *CNS* variety were equally chlorotic in the 1/50 *C* extract. In contrast, chlorosis of Lee in 1/100 concentration was as severe as in the 1/50, but *CNS* was free of chlorosis. In some lots of *C* extract, the Lee variety was as chlorotic in 1/200 as in 1/100 concentration; in other lots, it developed no chlorosis at 1/200, and only moderate chlorosis at 1/100.

Responses of other plants. Seedlings of 37 plant species in addition to soybeans were grown in 1/100 nodule extracts in the same manner as soybeans and scored for chlorotic response. Although all were evaluated on at least two occasions, the results do not necessarily indicate that the species which developed no chlorosis are resistant to the causative substance. All species were handled uniformly without effort to develop a technique particularly suited to a given species. It is quite possible that the technique employed was a limiting factor with some species but not with others.

Responses of the 38 species employed are summarized in Table 1. Of the seven species showing severe chlorosis, *Sorghum vulgare* showed onset of chlorosis two days after initial exposure, and the other six after three days. Average number of days for onset of chlorosis for the thirteen species listed as moderately chlorotic was 8·2, and for those listed as slightly chlorotic, 10·3 days. Seedlings of *Phaseolus vulgaris* and *P. lunatus* developed a mottled appearance after three weeks of exposure.

Chlorotic and normal seedlings of *Trifolium pratense* and *Sorghum vulgare* are shown in Fig. 1. Characteristics of seedling chlorosis for species other than soybeans were in general similar to those previously described for soybeans[2]. The chlorosis was restricted to new growth. Normal green leaves once fully formed did not develop chlorosis afterwards. In *S. vulgare* chlorosis developed first at the base of the second leaf and the entire leaf became chlorotic within a few days, but the first leaf remained green.

Damage to roots and general retardation of growth similar to those described for soybeans were observed to varying degrees with other species. *Carthamus tinctorius* and *Gossypium hirsutum* appeared to be particularly susceptible, although neither developed chlorosis. Growth of soybeans in fresh *C* extract that had been filtered through a bacteriological-grade sintered glass filter was more rapid and chlorosis more severe than that of seedlings in unfiltered extract. However, this was not true for autoclaved extracts. Root damage caused by autoclaved extracts was not associated with various fractions separated by filtering or centrifuging.

Table 1. SUSCEPTIBILITY OF SEEDLINGS OF VARIOUS SPECIES TO A CHLOROSIS FACTOR IN SELECTED SOYBEAN NODULES

Severely chlorotic
  Allium cepa, Digitaria sanguinalis, Sesamum indicum, Sorghum vulgare, S. vulgare (Sorgo), *Trifolium pratense, T. subterraneum.*
Moderately chlorotic
  Cucumis sativus, Cucurbita pepo, Glycine max, Linum usitatissimum, Lotus corniculatus, L. uliginosus, Medicago sativa, Oryza sativa, Sorghum sudanense, Trifolium incarnatum, Vigna sinensis, Zea mays, Zinnia elegans.
Slightly chlorotic
  Avena sativa, Lycopersicon esculentum, Vicia villosa.
Questionably chlorotic
  Phaseolus lunatus, P. vulgaris.
Non-chlorotic
  Amaranthus retroflexus, Arachis hypogaea, Brassica oleracea var. *acephala, B. rapa, Carthamus tinctorius, Festuca rubra, Gossypium hirsutum, Hordeum vulgare, Lolium multiflorum, Lupinus angustifolius, L. luteus, Raphanus sativus, Triticum aestivum.*

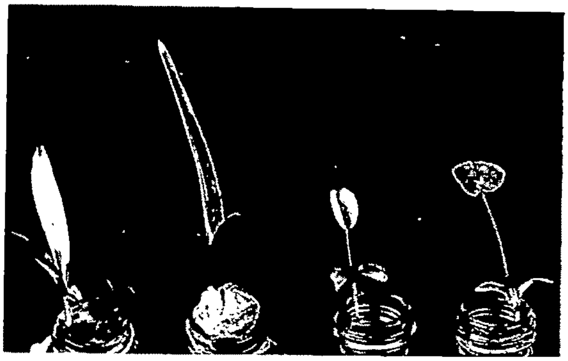

Fig. 1. Seedlings in 1/100 extracts of nodules from chlorotic and normal soybean plants. Left to right: *Sorghum vulgare*, chlorotic and normal; *Trifolium pratense*, chlorotic and normal

The several experiments indicate that the water-soluble substance causing chlorosis is an entity differing from the substance causing toxicity.

S. vulgare seedlings exposed to 1/50 *C* extract for as little as 8 hr. before transfer to distilled water showed slight chlorosis by 48 hr. after the original exposure but recovered by the end of four days. Seedlings left in the extract for 24, 28, 32, 48, 50, 56, 72, 76 and 80 hr. developed progressively more intense chlorosis, some of which persisted until the termination of the experiment on the twelfth day. With 1/100 and 1/200 concentrations, the minimum exposure time was 24 hr. rather than 8 hr.

S. vulgare seedlings in mixed extracts containing varying amounts of *N* and *C* nodules developed chlorosis in proportion to the concentration of *C* nodules in the mixture. A given concentration of *C* nodules in the mixture resulted in chlorosis equal to that of the same concentration of *C* nodules alone. Chlorosis of seedlings in 1/100 *C* extract in distilled water was comparable in speed of onset and severity with that of seedlings in 1/100 *C* extract in complete nutrient solution. As with soybean plant cultures, there was no evidence that chlorosis when present was due to lack of essential nutrients in the substrate.

Other substances reported to cause chlorosis in plants were evaluated using the techniques of the present study. The chlorosis produced by nodule extracts does not appear similar to that produced by streptomycin sulphate[4] or by biuret and ammonium nitrate. With soybean nodule extracts, negative results were obtained from placing extract in leaf whorls of *Zea mays* and *S. vulgare* seedlings in the manner described by Curtis[5].

PHYSICAL SCIENCES

Phase Characteristics of Radio Signals received via the Ionosphere

A RADIO wave after reflexion from the ionosphere may be considered to consist of a specular component and a varying diffracted component[1], the latter being the result of random scattering from a large number of moving irregularities. If the effect at a point on the ground is considered, the diffracted component may be regarded as a cone of radiation having its apex at the point on the ground and its base spread over a large area of the ionosphere. The specular component appears as a coherent wave the arrival path of which is assumed to be along the axis of the diffraction cone and changes direction slowly compared with the fading rate of the signal[2]. Information concerning the amplitudes of the specular and diffracted components of a radio wave and of the angular spread of the cone of rays forming the diffracted component is an important factor in the design of some types of receiving aerials. This information may be obtained from the probability distribution of the phase-difference between the two signals which result from the reception of the radio wave at two aerials spaced apart by a known distance.

By spacing the aerials so far apart that the spatial phase-correlation in the diffracted component in the signals at the two aerials is negligible, the ratio of the power in the specular component to that in the diffracted component may be measured. Phase measurements provide a more sensitive method of detecting small specular components than amplitude measurements since the Rayleigh distribution of amplitude is not altered materially by the presence of a specular component unless its power is several times that of the diffracted component[1].

Using a result given by Rice[3] in his work on random noise, it may be shown that the combined probability distribution for the phase φ and amplitude R of the signal at one aerial is :

$$p(R,\ \varphi) = \frac{b^2 R}{\pi} \exp[-b^2 (R^2 + 1 - 2R \cos \varphi)]$$

where amplitudes are measured in terms of the specular component and where b^2 is the ratio of specular component power to diffracted component power. The phase-probability distribution may then be shown by integration to be :

$$p(\varphi) = \frac{1}{2\pi} \exp(-b^2) \times$$

$$[1 + b\pi^{1/2} \exp(b^2 \cos^2 \varphi) \cos \varphi \{1 + \operatorname{erf}(b \cos \varphi)\}]$$

An approximation to this distribution may be made by using a normal distribution with the skirts outside the range of variate $-\pi < \varphi \leqslant \pi$ folded over and added to the distribution within this range. The (unrestricted-variate) probability distribution for the phase-difference φ_d between two aerials is then a similar distribution having twice the variance of the unrestricted-variate distribution for one aerial if the correlation is zero.

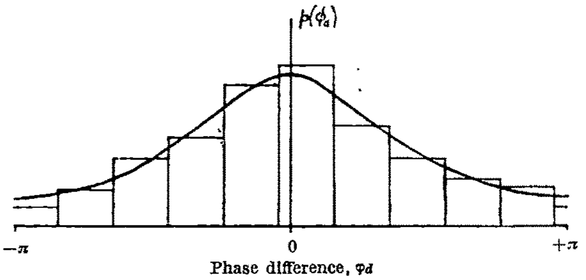

Fig. 1. Theoretical and measured phase probability distributions. Aerials widely spaced (26·0λ). WWV, 20·00 Mc./s. 1400 hr. February 10, 1958

With closer spacing between the aerials, measurements of the phase correlation between the signals enable the angular spread of the cone of rays forming the diffracted component to be estimated. The theory used in this case is similar to that used for direction-finding studies[4,5] with a correction applied to allow for the effects of the specular component.

Phase measurements of the type described have been made using a phase-distribution analyser. In this apparatus, the signals at the two aerials are changed in frequency to 1 kc./s. in three stages, common oscillators being used in order to preserve the phase difference between the signals. The 1-kc./s. signal derived from the first aerial is squared and differentiated to produce a pulse each time the waveform passes through zero in a positive direction. This pulse is arranged to open a gate which closes automatically after an interval of 0·1 msec. The closing of the first gate opens a second gate which also closes automatically after a similar interval, and this process is repeated through a chain of ten gates. The 1-kc./s. signal derived from the second aerial also causes a pulse to be generated each time the waveform passes through zero in a positive direction. This pulse is applied simultaneously to the ten gates associated with the first aerial and it will pass through one of the gates, depending on the phase difference between the signals at the two aerials. Ten counter units, each associated with one of the gates, are arranged to operate from the pulses passing through the gates so that after a suitable interval the numbers

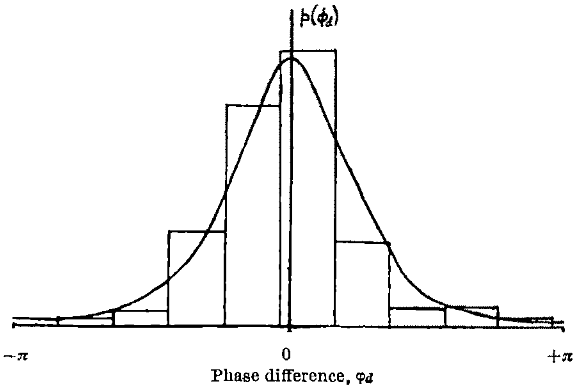

Fig. 2. Theoretical and measured phase probability distributions. Aerials close together (2·2λ)

displayed by the counters show the phase-difference distribution on a grouped-frequency basis.

The main advantage of this type of apparatus is the high rate of sampling which enables the probability distribution for several different aerial spacings to be determined before the effects of ionospheric tilting[2] produce significant changes in the statistical properties of the signal. Moreover, the distributions are displayed directly without the necessity for analysing chart records.

Typical 1-min. sample distributions are shown in Figs. 1 and 2 together with the theoretical distributions. The measurements were made on the standard frequency transmitter WWV (Washington, U.S.A.) operating on 20 Mc./s. at a time when a musa[6] receiver operating on 19·82 Mc./s. indicated that the transmission was virtually single-path. In Fig. 1, the peaking of the distribution was caused by the effects of a specular component alone. In Fig. 2, correlation in the diffracted component reduced the spread of the distribution still further. In the example quoted, the ratio of specular to diffracted power (b^2) was found to be 0·25, while the standard deviation of the angular spread of the diffraction cone in the vertical plane was approximately 6°. The vertical arrival angle derived from the means of the phase-difference distributions was 15°.

Electric Strength and High-Field Conduction Current in *n*-Hexane

SEVERAL investigations of the electric strength and high-field conduction of *n*-hexane and similar hydrocarbon liquids have been made in recent years, and reproducible measurements have been reported, for example, by Lewis[1], Sharbaugh, Crowe and Cox[2], and by House[3]. New experiments of mine, however, indicate that nearly all these results were strongly influenced by the presence of dissolved oxygen.

Samples of dry filtered *n*-hexane were prepared using techniques described earlier[1,3] with the important addition that the liquid could be well degassed by evacuating the closed distillation system to about 10^{-2} mm. mercury with the liquid cooled to -90° C. The liquid could be maintained in the test cell in this degassed state or saturated with dry gas as required. The electric strength and conduction measurements were made with highly polished spherical electrodes (1 cm. diameter), 50μ apart, using either direct or 1·5 μsec. rectangular pulse voltages and adopting similar techniques to those given in refs. 1–3.

Typical results chosen from a large number of repeatable tests are given in Table 1 and demonstrate that when the air or oxygen content of the liquid is large the strength is high and the coefficient of variation small. In these conditions the results are in close agreement with those reported earlier[1,3]. With degassed and nitrogen-saturated liquid the mean strengths are much lower, although the first few measurements with degassed liquid and fresh electrodes invariably gave high strengths. It was possible to change the liquid in the test cell from a degassed to an oxygenated state and vice versa several times with the electrodes unchanged and still maintain the strengths quoted in Table 1. It is important to note that the strength of a liquid with high air content showed no dependence upon pressure, in agreement with previous observations[1]; but for degassed liquid the strength decreased rapidly as the pressure was reduced below the atmospheric value.

Table 1. THE INFLUENCE OF GAS CONTENT ON THE ELECTRIC STRENGTH OF *n*-HEXANE. VALUES QUOTED ARE THE MEANS OF NOT LESS THAN TEN CONSECUTIVE MEASUREMENTS

Test voltage	Test liquid	Electrodes	Mean strength (MV./cm.)	Coefficient of variation (per cent)
d.c.	Degassed	Chromium	0·88	17·1
d.c.	High air content	Chromium	1·33	6·4
d.c.	High oxygen content	Chromium	1·33	6·2
d.c.	High nitrogen content	Chromium	0·89	10·7
1·5 μsec. pulse	High air content	Stainless steel	1·55	12·3
1·5 μsec. pulse	Degassed	Stainless steel	0·90	5·5

The air content also influences the high-field conduction current. With degassed liquid the current fluctuated more and more violently as the field was raised and showed little tendency to become stabilized with time. On the other hand, a liquid with a high air content at atmospheric pressure was found to have a stable conduction current which could be measured at fields right up to 1·2 MV./cm. After the first voltage application reproducible current-voltage curves as in Fig. 1 could easily be obtained. It can be seen that the current is about a quarter of that reported by House[3] for the same electrode conditions. Even with hexane of commercial purity, curves almost identical to those given by House can be obtained provided the air content is large, without the necessity of a long conditioning process.

It is concluded that the oxygen content plays a vital part in determining the electric strength and conductivity of *n*-hexane. Experiments are proceeding to determine more precisely the role of oxygen

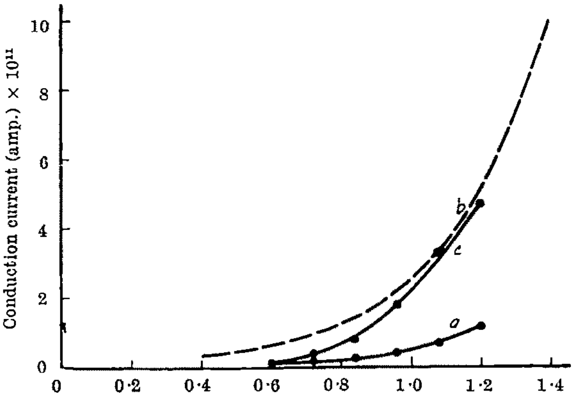

Fig. 1. Conduction current in *n*-hexane as a function of mean stress for a 50-μ gap and stainless steel electrodes. *a*, Spectroscopic grade hexane, air saturated at 760 mm. mercury; *b*, spectroscopic grade hexane, as reported by House (ref. 3); *c*, commercial grade hexane, saturated with air at 760 mm. mercury

and other gases in the breakdown processes, and the results will be published in due course. The present results are sufficient to show, however, that most of the high and reproducible values of the breakdown strength reported hitherto referred to *n*-hexane containing a substantial proportion of dissolved oxygen.

I wish to thank Prof. M. W. Humphrey Davies for the facilities made available to me. Thanks are also due to Dr. T. J. Lewis and other colleagues in the Department.

A Proposed Method for the Measurement of the Velocity of Light

THE precision of optical methods of measuring the velocity c of electromagnetic radiation in free space is restricted by the upper limit of the frequency at which a light wave may be amplitude-modulated. Bergstrand[1], in his recent measurements, used a modulation frequency of 10 Mc./sec. and consequently his base-lines were several km. long. The highest modulation frequency so far reported seems to be 300 Mc./sec. by Rao and Murty[2] using diffraction by ultrasonic waves in a crystal. It would be desirable to increase this limit so that an optical standard of length could be used directly in a determination of c. The correlation of photons in coherent light, which now seems well established[3], eliminates the necessity for a direct modulation of a light source. Two wave trains of optical frequencies ν_1 and ν_2, falling on a photosensitive surface, will give[4] a component in the photo-current at a frequency $(\nu_1 - \nu_2)$. If the wave trains are divided at a half-silvered mirror and fall on two photocells P_1 and P_2, the outputs S_1 and S_2 of these cells at a frequency $(\nu_1 - \nu_2)$ may be added and will interfere to give an output S_3, the amplitude of which depends on the relative phases of the two signals S_1 and S_2. It may readily be shown that if P_1 is kept fixed and P_2 is moved radially away from the source, the amplitude of S_3 will have minima separated by a distance $\frac{1}{2}c/(\nu_1 - \nu_2)$ if the source can be considered to be a distant point.

At the moment the method is impracticable because the signal-to-noise ratio achievable with existing light sources would be far too small. The proposed development[5] of a maser working in the visible region would, however, yield a light source with a very much smaller frequency width than has hitherto been obtained. Ideally, for the application suggested here, the source should emit light in two narrow bands $(\nu_1 - \nu_2)$ apart, each having a frequency width very much narrower than $(\nu_1 - \nu_2)$. The latter criterion, according to the example taken by Schawlow and Townes[5], could, if $(\nu_1 - \nu_2)$ were of the order of 1–10 kMc./s., be achieved in the optical maser. The separation of the two components could be obtained by the Zeeman splitting of the line emitted by the maser. The use of such a high value of $(\nu_1 - \nu_2)$ precludes the use of the conventional photomultiplier ; but there seems no reason why a suitable photosensitive device[4] should not be designed for use at such frequencies.

The ultimate precision of this proposed method depends on the signal-to-noise ratio which can be achieved when : (*a*) the sizes of the light source and of the detecting surfaces are restricted within narrow limits, and (*b*) the frequency $(\nu_1 - \nu_2)$ is defined by a narrow-band receiver. Successful operation of the optical maser would allow the precise determination of c in the visible region over much shorter baselines, and possibly with higher precision than has hitherto been achieved. It would also provide a light source which would allow an even more convincing demonstration of photon correlation than that of Twiss, Little and Hanbury Brown[3].

An Experimental Method for Diffusion and Extraction Studies across the Liquid–Liquid Interface

THE prototype apparatus shown schematically in Fig. 1 offers a promising experimental approach for diffusion and extraction studies across the interface between certain aqueous–organic systems uncomplicated by diffusion control in the adjacent bulk phases. It may also prove an effective probe of factors which influence the behaviour and 'structure' of the interface. The apparatus is operated in the following way. The substance being extracted (with tracer) is dissolved in 1 cm.^{3} of static aqueous phase placed so the aqueous surface formed at the bottom of the 'Teflon' slit (0·25 in. × 0·001 in.) is oriented lengthwise across the width of the rim, and about 0·006 in. above the wheel. Individual organic drops, at 1–5 drops/sec., are dropped on the 'Teflon' rim spinning at 10–200 r.p.m. Each drop is squeezed past the slit where it makes brief 'contact' with the aqueous phase before being almost entirely dragged away from the slit, wiped off, and collected at the bottom of the wheel. The activity/cm.^{3} of substance in the extract multiplied by the rate of production of drops is a measure of the 'apparent extraction rate', a parameter sensitive to the concentration of constituents involved in the extraction process.

In a study at 100 r.p.m. of the simultaneous extraction of radioactive iron(III) and cæsium(I) from a 1 M nitric acid/water solution with pure tributyl phosphate, the ratio of the activity of cæsium to that of iron in the extract was 0·80 ± 0·02 compared to the original value in water of 1·18 ± 0·03. The activity/cm.^{3} in this extract was about 10^{-3} times that of the aqueous phase, but it was about ten times more than is picked up by tributyl phosphate in a single equilibrium extraction with the same volume. These results indicate that a 'stable' interface with diffusive flow across it was achieved and that a differential rate of extraction in favour of iron(III) over cæsium(I) was obtained. Furthermore, the ratio of cæsium to iron in the extract differed markedly from the equilibrium value

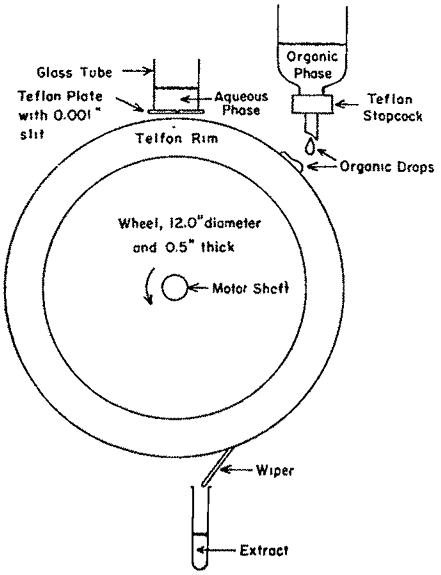

Fig. 1. Schematic cross-section of 'steady-state' interfacial extraction apparatus

of 2·0 for this phase, which is good evidence that the extraction depends on irreversible processes. Using tributyl phosphate/kerosene mixtures for the organic phase, the apparent extraction rate of iron(III) is dependent on the concentrations of iron(III), nitric acid and tributyl phosphate. For example, the rate is approximately fifty times greater using pure tributyl phosphate than using pure kerosene under similar conditions. These qualitative results indicate the feasibility of determining the form of the kinetic rate expression and testing the mechanism of extraction processes by this approach.

Thus it is possible to maintain an aqueous-organic interface within a 'Teflon' slit while mechanically pulsing it as frequently as every 0·2 sec. with a fresh drop of organic phase. Each drop apparently perturbs the interfacial region for a period which can be varied easily from 10^{-1} to 10^{-3} sec., during which mechanical agitation in the bulk phases adjacent to the interface must occur. These actions help to prevent diffusion in the bulk phases from limiting diffusion across the interface. It is believed that the net effect of frequent pulsing is to establish a relatively constant gradient of concentration, with a 'sink' on the organic side, so that diffusion across the interface is essentially unidirectional. The periodic pulsing of successive drops appears to be quite crucial to the success of this method, for the interface is unstable with a continuous flow of organic phase.

For processes between a two-phase liquid system, the method is somewhat analogous to the pulsing methods described by Eigen[1] for homogeneous systems. If it can be perfected, it may be possible to measure extraction rates and the form of the rate expressions for diffusion in both directions across the interface and thus obtain ratios of rate constants independent of uncertain quantities such as 'phase contact time' and the detailed geometry of the interface. Such rate constant ratios should be related to the distribution coefficients obtained in equilibrium extractions.

The simple geometry of the apparatus lends itself to certain modifications to make it an even more useful probe of interfacial phenomena. For example, the extract can be recirculated for slower diffusion processes like those through ion-exchange and biological membranes. It can also be adapted for extraction studies with a temperature gradient imposed across the interface. One last feature should be mentioned; because 'Teflon' is a non-conductor and can be charged, there exists the possibility of pulsing the interface with a variable electric field and of testing this effect on the extraction process. The instrument is now being modified for a more comprehensive investigation of its potentialities.

I am indebted to the Analytical Chemistry Division, ORNL, Oak Ridge, Tennessee, for the construction of the apparatus and the use of its facilities to obtain these experimental results while I was a summer participant supported by the Oak Ridge Institute of Nuclear Studies from June to September 1958. I also wish to thank B. A. Soldano, W. Baldwin and D. Harrison for valuable discussions.

Measurement of the Flocculation of Suspensions

AT the Third International Rheological Congress held in Germany in September 1958, Prof. R. Fahraeus, in a paper entitled "The Influence of the Rouleau Formation of the Erythrocytes on the Rheology of the Blood", described a method which he had developed for measuring the degree of coagulation present in a blood sample. The procedure was to filter the blood through a stack of filter papers and to measure the quantity retained on each. The greater the coagulation of the blood, the less the number of papers through which it could penetrate.

I have recently tried this technique for measuring the degree of flocculation of a clay suspension. 100 ml. of a 2 per cent suspension (by weight) was poured into a pressure filter which contained a stack of papers 9 cm. in diameter and a pressure of approximately 15 lb./sq. in. was applied. At the top of Fig. 1 may

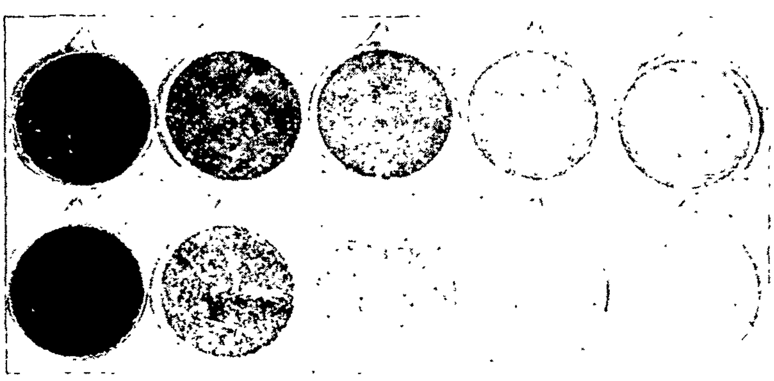

Fig. 1

be seen the successive papers obtained with a suspension (in distilled water) of a coal-measure shale from the Grove seam in the West Midlands. At the bottom are papers obtained after 5 ml. of a 1 per cent solution of potash alum had been added to 100 ml. of the same suspension in order to produce flocculation of the solid matter. The reduction in the penetration of the filter papers (Whatman No. 4) is quite evident and should be amenable to quantitative measurement.

Thus it appears that Prof. Fahraeus's technique could offer a method not only for measuring the coagulation of blood but also for the flocculation of shale and clay suspensions.

Etch Pits on Calcite Cleavage Faces

This communication describes some of the effects observed on calcite cleavage faces after etching with dilute acid. Puchegger[1] has reported etch pits which formed a rib-like pattern on either side of scratch marks made on calcite. More striking features are described here.

Rhombohedral crystals, freshly cleaved from a large block of natural calcite, were etched and examined on each face in turn. Etching was carried out in 1 per cent nitric acid, after which the crystals were washed with distilled water, ethanol and carbon tetrachloride, and dried. Etching times varied from 5 sec. to 5 min. The crystals were examined and photographed on a Vickers projection microscope using oblique illumination by a mercury-vapour lamp with yellow-green filter.

The same general features were found on each face and no features were found to be peculiar to any single face or pair of opposite faces. Numerous etch pits were observed occurring singly, in small groups, and in lines of overlapping pits. No pits were observed on unetched faces. Three types of pit were observed; three-sided 'flat iron' pits depicted in Fig. 1*a*, referred to hereinafter as type 1; four-sided pits (Fig. 1*b*), type 2; and five-sided pits (Fig. 1*c*), type 3. Types 2 and 3 predominated. Steps were observed on the faces of many of these pits and may be seen in Fig. 1*d*. Some pits retain their shape for long etching times, others cease to increase in depth relative to the general surface-level after a few seconds etching and then only increase in area to give flat-bottomed pits, some of which may be seen in Figs. 1*a* and *b*. These pits eventually overlap others and fade out to leave a shadowy outline. New pits sometimes start to grow in the flat bottom of an old one. Some pits persist for several minutes etching time and become visible to the naked eye; such pits have very rounded sides. A few highly pitted regions were observed. They appear within 5 sec. etching and persist with little change in configuration for 3 min. or more (Fig. 1*e*). These pits were all of type 3; but in the figure dark shadow makes it difficult to distinguish the intersection of two of the faces.

Visible fracture planes in the crystal, both parallel to and along the diagonals of cleavage faces, etched into deep grooves (Fig. 1*f*) with a rib structure similar to but more pronounced than that observed by Puchegger[1]. These grooves sometimes contain a few deeper pits, as may be seen in Fig. 1*f*.

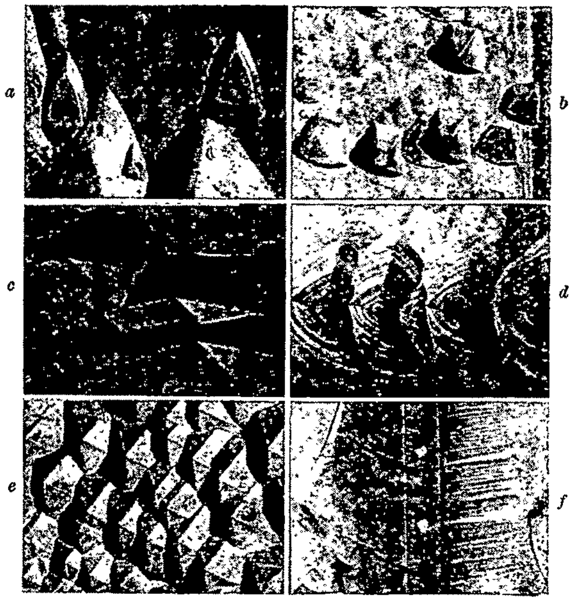

Fig. 1. *a*, Three-sided etch pits, type 1, 90 sec. etching; *b*, four-sided etch pits, type 2, 5 sec. etching; *c*, five-sided etch pits, type 3, 30 sec. etching; *d*, line of overlapping pits, 45 sec. etching; this line extended for more than 2 mm. on the crystal; *e*, highly pitted region, 60 sec. etching; *f*, etch groove at fracture plane—note width of ribbed region and pits in groove. (All *c*. × 100)

The fact that some pits lie in lines across the crystal (Fig. 1*d*) suggests that they are formed by preferential etching at the site of dislocations in the crystal[2]. The highly pitted regions would be regions of high disorder. The width of the ribbed region in Fig. 1*f* seems to indicate that slip along a fracture plane in the crystal disturbs a large region on either side of the plane.

The steps on a pit face make it possible to determine if that face is flat or curved, if it is presumed that all steps are parallel to the original surface before etching. All faces on pits of type 3 are flat, all pits of type 2 have at least one curved face, while all faces on pits of type 1 are curved. Pits of types 1 and 2 are probably degenerate forms of type 3 pits. Replacement of a pair of flat faces in type 3 by one curved face would give type 2; at the same time two other faces often become slightly curved. Type 1 pits would be formed from type 2 by continuing two faces to meet at a point.

It is difficult to envisage a mechanism whereby a five-sided etch pit can arise in a rhombohedral crystal. In view of the importance of etch pits to dislocation theory, I feel it is worth directing the attention of others to these effects at the present time.

I am indebted to Mr. W. T. Denholm for discussions.

A Micrographic Study of Wear of Graphite

The sheet-structure of graphite is well known[1]: upon microscopic examination of crystalline fragments, individual sheets exhibit some properties of a tough membrane when not torn transversely. Individually they may be lifted or peeled to uncover a flat surface, which is highly reflecting, and in thin layers transparent.

These properties make graphite ideally suited for microscopic observations of its wearing characteristics during the sliding process.

The details of this process for graphite had not been apparently discovered. For example, it was not known whether wear accrues from the mechanical action of edges, the adhesion through edge surfaces or across massive facial areas, the tooling action of disoriented crystals, or by other unexpected effects.

Observations have been made here on natural graphite crystals oriented on the stage of a microscope under bright field epi-illumination. Initially the basal plane of the crystal was mounted rigidly and held flat and normal to the incident light beam. With selected adjustments of the illumination, steps, faults and surface impurities became prominent, and slight disturbances to a shallow depth within the crystal were found to produce faint shadows indicating the nature and extent of the stresses or damage.

During this work at magnifications up to 320, the graphite faces were explored by metal micro-probes or polished needles using the smooth conical section near the tip. The geometry of the arrangement made possible the estimation of the real contact area in relation to the area visibly disturbed by the contact.

This disturbed area was found to be very much greater than that bounded merely by the contact dimensions of the probe. Upon application of pressure of the probe against the graphite, a few sharp shadow lines frequently developed within the graphite surface adjacent to the contact spot. These spread to the sides or in advance of the probe and travelled with it as it traversed the basal plane surface. These shadow lines were usually straight, and extended to distances as much as a hundred times the contact radius. Some were completely elastic, disappearing upon withdrawal of the probe or oscillating back and forth if the probe was made to vibrate gently upon the surface.

By interference microscopy it was found that the shadow lines in representative cases could be the boundaries of basal plane area which had undergone minute localized tilting near the contact region, amounting to a few hundred angstroms of tilt across the entire field of view.

These optical line patterns on the graphite undergoing rubbing are interpreted tentatively as fault or dislocation regions at the intersectional boundaries between original planes and disturbed planes. This interpretation implies reversible atomic separations transversely through the basal planes in patterns sufficiently broad to be observed as narrow lines with an optical microscope. Disturbances of this kind should involve a contribution to the frictional work, and they indicate one of the characteristic features in the sliding process which may precede the onset of wear.

The appearance of these optical line patterns emanating beyond the region of real contact suggests that the shearing and ploughing terms, generally accepted as descriptive of the main processes involved in sliding solids, may not be sufficient to describe the wear and friction occurring on the surfaces of lamellar solids. A new description of the graphite-wearing process following from the detailed microscopic observations will appear in due course.

Low-temperature Specific Heats of Body-centred Cubic Chromium–Iron and Chromium–Manganese Alloys

The electronic structure of the transition elements in the metallic state is not yet fully understood. It may be hoped that additional information with regard to the electronic specific heat coefficients and other physical properties of these elements, as well as of their alloys, will help in the interpretation of their structure.

On the basis of the band structure of the transition elements and of the usual interpretation of the electronic specific heat coefficient, it should be possible to trace the shape of the partially filled *d*-band, that is, the density of states as a function of the electron concentration, by determining experimentally the electronic specific heat coefficient γ for a series of solid solution alloys of a given crystal structure.

In the present work, low-temperature specific heats were determined for body-centred cubic binary solid solutions in the chromium–iron and chromium–manganese systems. Specific heats were measured in the temperature range of 1·6°–4·2° K. to an estimated accuracy of ± 2 per cent for most alloys. For a few alloys, where the specific heat depends very sensitively on the alloy composition, the accuracy may have been as low as ± 5 per cent. The alloy specimens were prepared by induction melting from electrolytically refined metals and homogenized by annealing for at least three days at 1,170° C. in a purified gas mixture of 92 per cent helium and 8 per cent hydrogen, and quenched to room temperature.

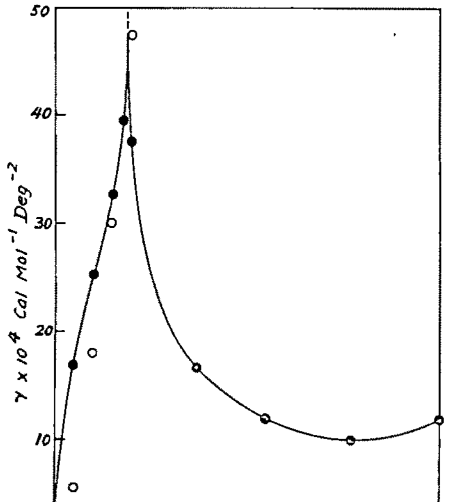

Fig. 1. Coefficient of temperature-linear term of low-temperature specific heat vs. electron concentration. ●, Chromium-iron alloys; ○, chromium-manganese alloys

The low-temperature specific heats were analysed by means of the usual C_v/T vs. T^2 extrapolation to $T = 0$, to obtain the coefficient γ of the temperature-linear term. These γ values are plotted in Fig. 1 as a function of the electron concentration. The γ for iron was measured and found to be in excellent agreement with the value reported by Keesom and Kurrelmeyer[1]. The γ for $Cr_{0\cdot44}Fe_{0\cdot56}$, as determined by Hoare and Matthews[2], is plotted in Fig. 1, and it fits very well the curve for chromium–iron alloys. A large peak occurs at $Cr_{0\cdot81}Fe_{0\cdot19}$, with a γ value more than ten times that of chromium[3]. The fact that similarly high γ values were found also for specimens in the chromium–manganese alloy series at corresponding electron concentrations suggests that the observed effect may be related to characteristic values of the electron concentration. However, it is as yet uncertain whether or not the γ-peak should be interpreted simply in terms of density of states. The work on the low-temperature specific heat and on other physical properties of these alloys is continuing.

Effect of Low Concentrations of Alcohols on the Interfacial Tension between Water and Hydrocarbons

A STUDY has been made of the effect of low concentrations of *n*-aliphatic alcohols on the interfacial tension of water against hexane and octane. For this purpose an apparatus was designed, based on the drop-volume method, which allowed the interfacial tension to be measured with an accuracy of 0·04 dyne cm.$^{-1}$ in rigorously purified systems. Determinations were carried out at 10°, 25° and 40° C.

The results of the measurements are best presented graphically; for the system methanol – water – hexane they are shown in Fig. 1. The ordinates represent $\Delta\gamma$, the deviation of the interfacial tension from that of the hydrocarbon – pure water interface. The first addition of a trace of methanol (10^{-11} mol. l.$^{-1}$) causes, at the lower two temperatures, an elevation of the interfacial tension. $\Delta\gamma$, after reaching a peak at about 1·2 dyne cm.$^{-1}$ (about 30 times experimental error), levels off at approximately + 0·4 dyne cm.$^{-1}$, before becoming negative. At 40° C., these effects have vanished.

A similar behaviour has been observed in the case of ethanol and *n*-propanol, but the peak decreases in height and is shifted to higher alcohol concentrations as the number of carbon atoms in the alcohol increases. *n*-Butanol exhibits entirely 'normal' behaviour at all three temperatures.

The systematic nature of the results is emphasized by tabulating: (1) the maximum elevation of interfacial tension, and (2) the threshold concentrations above which normal, preferential adsorption of the solute occurs. This is done in Table 1.

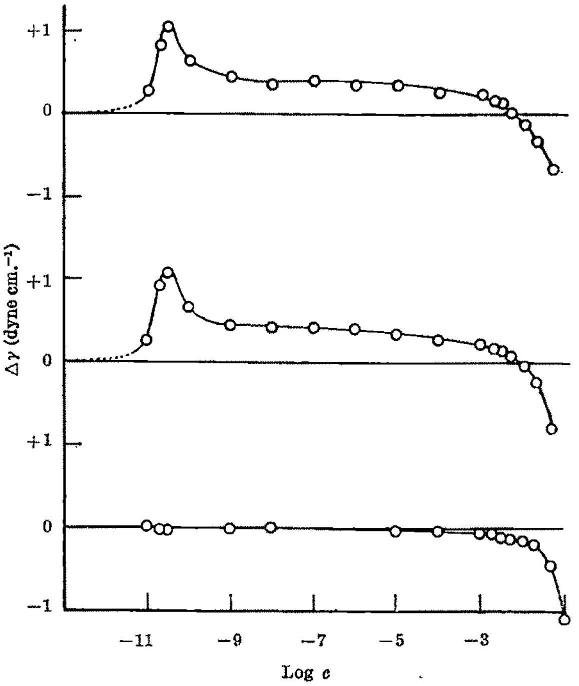

Fig. 1. Interfacial tension/concentration isotherms. Top, 10° C.; middle, 25° C.; bottom, 40° C.

When the thermodynamic functions associated with the generation of 1 cm.^{2} of interface, relative to those for the alcohol-free system, are calculated, it is found that the disappearance of the abnormalities between 25° and 40° C. is accompanied by an exaltation in ΔH, and an even more striking exaltation in $T\Delta S$. In order to ascertain whether the abnormalities disappear over a range of temperatures or at some definite temperature, interfacial tensions of several systems have been measured at temperatures between 25° and 40°. Similar measurements have also been made on the system hexane – pure water. In every case it is found that the abnormal behaviour disappears very suddenly between 33° and 37°. Even for the system hexane – water itself the slope of the interfacial tension/temperature curve exhibits a maximum in the same temperature-range. Fig. 2 shows the effect of temperature on the entropy (or relative entropy) of interface formation $\left(-\Delta S = \frac{d\gamma}{dT}\right)$. It is of interest to note that a similar type of curve is obtained for the entropy of surface formation of water, derived from the surface tension of water.

To show that the observed effects are not due to some peculiarity of the hydrocarbon normally used, determinations were carried out using *n*-octane as the oil phase. Identical results were obtained with this hydrocarbon. The abnormal effects are in all cases

Table 1

Alcohol	(1) Maximum $\Delta\gamma$ (dyne cm.$^{-1}$)		(2) Threshold concentration (mol. l.$^{-1}$)	
	10°	25°	10°	25°
MeOH	1·08	1·08	$6\cdot7 \times 10^{-3}$	$8\cdot5 \times 10^{-3}$

METEOROLOGY

Volcanoes as a Source of Atmospheric Ice Nuclei

In order to determine the nature and the concentration of ice-forming nuclei in the atmosphere, which are considered to play an important part in the initiation of rain, we have been carrying out, in Tokyo since April, measurements of the concentration of ice nuclei by means of an ice nuclei counter similar to that of Bigg[1]. The concentration is measured at temperatures of − 13° C., − 15° C. and − 20° C. It was found[2] that the concentration of ice nuclei was low in maritime air masses and high in the air masses which reached Japan from arid or semi-arid regions of the continent of Asia. Very high concentration in spring was found to be associated with the arrival of dust consisting of loess particles originating from the ground of the arid region of north China. The result of our experiment on loess particles which fell in Japan shows that they are effective as ice nuclei at temperatures below − 13° C. Despite the general tendency already mentioned, the concentration of ice nuclei in the atmosphere increased occasionally even in maritime air masses.

This phenomenon has been found to be related with eruptions of active volcanoes in Japan. In June and July 1957, Volcanoes Mihara, Aso, Suwanose and others were very active and erupted intermittently, ejecting ash high up into the atmosphere. The very high concentration observed during the period June 25–July 5 is considered to be due mainly to the ash from Volcano Mihara, which is at a distance of 100 km. to the south of Tokyo. The event which showed the most distinct and direct effect of volcanic ash was the eruption of Volcano Asama at 20h. 50m. on November 10, 1958. The eruption was the most violent among those in the past twenty years. After this eruption, Mt. Asama emitted coloured smoke (instead of white smoke as usually) continuously and erupted intermittently. The concentration of ice nuclei in the air observed in Tokyo is shown in Fig. 1, in which marked increase (40 times more than usual) in the nuclei concentration after the eruption is seen. The increase of concentration was large, but smaller than might have been expected from the scale of the eruption. It is considered to be due to a south-west wind, which carried most of the ash towards the north-east, while the measurement was made in Tokyo, which is situated to the south-east of the volcano. On November 12, the wind veered, smoke being observed to flow eastward and the concentration of nuclei increased. Minor peaks in the concentration seen in Fig. 1 were associated with the smaller eruptions which followed the violent one. The results of our laboratory experiments on volcanic materials from active volcanoes in Japan show that their property of serving as ice nuclei differs according to the nature of the material (Fig. 2) and that ash from Volcano Asama is very effective as previously described[3,4].

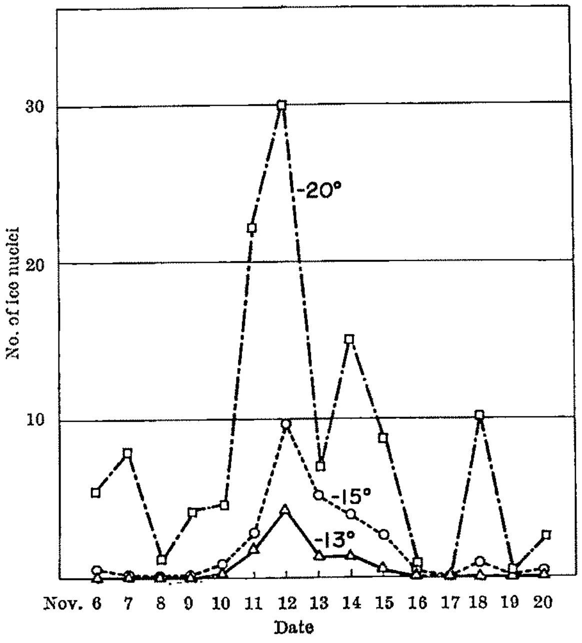

Fig. 1. Increase of the concentration of atmospheric ice nuclei due to eruptions of Volcano Asama. Measurement was made in Tokyo, 140 km. from the volcano. The greatest peak of the concentration corresponds to the most active period of eruptive activity

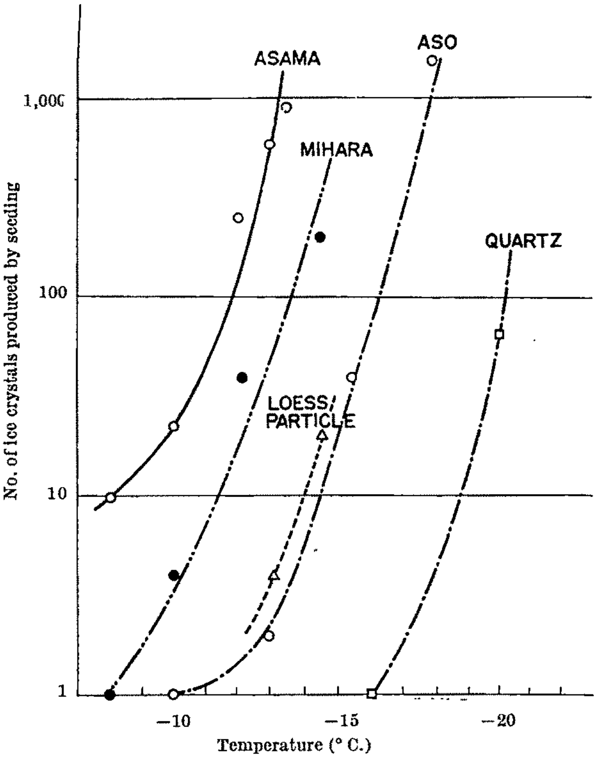

Fig. 2. Number of ice-crystals formed when 10 mgm. of each material is seeded into a cold box kept at the temperature indicated

Based on the statistical study of the relation between the amount of rainfall and the eruptions of Volcano Asama, we have suggested[3] that volcanic ash might be one of the important categories of ice nuclei in the atmosphere and play an important part in precipitation. The annual rainfall in the regions to which ash was carried by wind aloft was significantly high in the years in which the Volcano was active, and also the daily amount was significantly high on the days with eruption and the days following eruption.

The facts mentioned above strongly support the idea that some of the active volcanoes in the world are important sources of active ice nuclei, which may influence precipitation on a large scale. It may be suspected that the volcanic activity of the Earth might have played a part in the climatic change. A more detailed discussion of the subject will be published elsewhere.

Organic Nitrogen in New Zealand Snows

The nitrogen balance in New Zealand presents some rather interesting problems. In native forest and commercial exotic forests no natural source providing appreciable increments of nitrogen to the soils has yet been established. The non-symbiotic nitrogen-fixing bacteria *Clostridium butyricum* have been found in some tussock grassland soils by Ross[1]; but their numbers are thought to be too low to account for extensive fixation. Stevenson[2] has presented evidence that some of the higher plants may themselves fix quantities of nitrogen [see also *Nature*, January 24, p. 223]. The possibility that some nitrogen is supplied via the atmosphere has been investigated by me. Snow was collected above the vegetation line to avoid possibility of contamination by plant or animal debris. This was done in preference to the more conventional rain-water sampling, which is open to large contamination errors. Since the samples were collected in the early and mid-winter there is little possibility of contamination with pollen. The analyses of snow collected from various parts of New Zealand are shown in Table 1. The samples of snow were either kept frozen until analysis, or treated on collection with toluene to arrest any bacterial activity.

As can be seen from Table 1, New Zealand snow may contain up to 0·23 p.p.m. of bound nitrogen. No nitrogen is found as nitrate or nitrite, which are the classical nitrogen-cycle contributions from the atmosphere (products of electrical discharges). Perhaps the most interesting point in the above results is that sometimes most of the nitrogen is found in the 'albuminoid'[3] or organic nitrogen fraction.

Table 1

	Nitrogen content of snow samples (ref. 3)				
	NO_3^- (p.p.m.)	NO_2^- (p.p.m.)	NH_4^+ (p.p.m.)	Organic (albuminoid) (p.p.m.)	Total (p.p.m.)
(1) Sample of snow collected April 26, 1958, at 6,000 ft. (tree line 4,000 ft.) during snowstorm on Mt. Ruapehu (100 miles from sea). Wind W.-S.-W.	0	trace < 0·002	0·08	0·15	0·23
(2) Sample of freshly fallen snow collected April 26, 1958, at 5,300 ft. on Mt. Ruapehu	0	trace < 0·002	0·03	0·2	0·23
(3) Sample of snow collected May 3, 1958, at 6,000 ft. (tree line 4,000 ft.) on Mt. Egmont (20 miles from sea)	0	0	0·03	0·1	0·13
(4) Sample of snow collected April 27, 1958, at 7,000 ft. on Tasman Glacier (above tree line 4,000 ft., distance from sea, 25 miles)			0·1	0·12	0·22
(5) Sample of rain collected in Wellington in southerly storm on April 26, 1958. Distance up-wind to open sea, 10 miles; altitude, 10 ft.	0	0·002	0·27	0·2	0·47
(6) Sample of snow collected July 20, 1958, at 5,750 ft. (tree line 4,000 ft.) during a snowfall on Mt. Ruapehu (100 miles from sea). Wind, N.-W.	0	0	0·2	0·04	0·24
(7) Sample of snow collected July 21, 1958, at 6,575 ft. Same fall as in (6)	0	0	0·33	0·07	0·40
(8) Sample of snow collected July 21, 1958, at 8,070 ft. Same fall as in (6)	0	0	0·2	0·02	0·22
(9) Sample of snow collected August 2, 1958, at 6,000 ft. during snowstorm on Mt. Ruapehu	0	0·001	0·02	0·09	0·11

Albuminoid nitrogen is not usually measured by those who study atmospheric chemistry[4], and when measured has generally been attributed to contamination, though its significance is becoming realized[5]. Since the samples described in this communication were freshly collected snow from regions where no plants or animals exist, contamination from these sources should be negligible. No insoluble inorganic material was visible in the samples, so that cyclic terrestrial dust could not contribute appreciably to the nitrogen found in the samples. This is further supported by the lack of nitrate in the samples. The samples were collected in early winter and thus the pollen contribution would be negligible. Thus it seems that precipitation, at least in New Zealand, does in fact contain organic nitrogen which does not arise from contamination. From considerations of the geographical position of the sampling points with their lack of population and industry, I believe that the nitrogen found in the samples has its ultimate origin in the ocean and does represent a net transfer of nitrogen from ocean to land. This will be discussed in detail in a future communication.

If the results shown in Table 1 are taken as representative of the annual precipitation, it suggests that several pounds of nitrogen per acre are being deposited on New Zealand each year from the surrounding ocean. This might represent a contribution to the nitrogen economy of New Zealand soils.

I wish to thank Mr. H. J. Wood of the Dominion Laboratory, Wellington, for the analyses and Mr. A. J. Heine and Mr. G. Pallo, Department of Scientific and Industrial Research, for collecting samples.

CHEMISTRY

An Autoradiographic Method for distinguishing Samples labelled with Phosphorus-32 and Sulphur-35

Gillies[1] has recently described a method for examining insects labelled with sulphur-35 or phosphorus-32. The specimens were covered with two pieces of X-ray film, and autoradiographs made in the usual way. The low-energy sulphur β-particles (0·167 MeV.) were found to blacken only one film, while the high-energy phosphorus β-particles (1·71 MeV.) penetrated the first film and blackened the second also.

This useful method can be simplified by using film coated with photographic emulsion on both sides, as are most commercial X-ray films. In this laboratory, Kodak 'Kodirex' film is used for autoradiography of paper chromatograms, and with this material the two isotopes can be easily distinguished. If there is sufficient blackening of the film (such as is shown in the figure in Gillies's paper), a matt appearance is observed in reflected light and it can readily be seen whether one or both sides are affected. This can also be seen, even after much smaller exposures, by removing a little of the emulsion from both sides with a blunt scraper, either on the wet film after processing or after softening the gelatin on a dry film by moistening with 2 *N* sodium hydroxide. Examination of the film during photographic development is also helpful. Blackening of one side will not show on the other side of an uncleared film.

Gross over-exposure of a highly active sample should be avoided, since under these conditions even sulphur-35 will produce visible blackening on the second side of the film.

As would be expected, the effect of γ-rays is much smaller than that of β-particles on such a thin, light material as X-ray film. Thus bromine-82, with a β-particle energy of 0·44 MeV., produces a comparatively small amount of blackening on the second side of the film, although it is also a hard γ-emitter; more is produced by iodine-131, which has an average γ-energy less than that of bromine-82, but a higher β-energy (0·61 MeV. for 87 per cent of particles).

From the β-energies, using the equation given by Whitehouse and Putman[2], the half-thickness for various isotopes has been calculated, and thence the fraction of β-particles that would pass through 'Kodirex' film (which has a surface density of about 28 mgm./cm.^{2}). Approximate values of this factor for a number of useful isotopes are: carbon-14 and sulphur-35, virtually nil; bromine-82, 0·23; iodine-131, 0·40; phosphorus-32, 0·82. These figures are consistent with the relative blackening of the two sides of the film judged subjectively, and suggest that it might be feasible to distinguish more than two isotopes by this method.

A Chromatographic Technique for studying the Mechanism of Surface Catalysis

Gas chromatography has successfully been applied in the field of catalysis by Emmett and his co-workers[1-3], where it is referred to as a "microcatalytic chromatographic technique". This involves placing a small catalytic reactor directly on top of a gas chromatographic apparatus and injecting a small quantity of reactant at the top of the reactor. The slug of the reactant passes through the reactor, into the chromatographic column, and out through the analytical system; thus a rapid survey of the activity of a given catalyst can be carried out. This communication describes another new chromatographic technique for studying the mechanism of catalysis, measuring adsorption during reaction.

The importance of adsorption measurements during surface catalysis has previously been emphasized[4]. The adsorption on catalyst surface during reaction cannot be estimated from the separate adsorption data of each gas involved in the catalysis. The adsorption during reaction also depends upon the rate-controlling step of the overall reaction. Accordingly, if we could estimate the adsorption during catalysis, this should provide information on the rate-determining step of the reaction.

The adsorption measurements during surface catalysis can be carried out using the principle of gas chromatography in the following way. The gaseous reactant passes through the chromatographic column charged with catalyst as a carrier gas such that not all the reactant would be consumed while it passes through the column. The sample gas is injected at the top of the catalyst column. The slug of the sample gas then passes through the catalyst on which the reaction occurs, and out through the analytical system, being carried by the reactant. The more strongly the sample gas is adsorbed the longer becomes the time of its retention. Accordingly, the adsorbability of the sample gas during the reaction can be estimated.

The separate adsorption of each gas on the catalyst can be estimated independently in a similar way using inert carrier gas instead of reactant, and from the dependence on temperature of the apparent retention time its heat of adsorption can be determined.

Palladium was deposited on 'Celite 545' according to the method described by Sano[5] in the ratio 1 : 20. The catalyst was charged in the adsorption column 12 m. long. The apparent initial retention times with various carrier gases and samples at 99° C. are listed in Table 1, where the rate of flow of the carrier gases was 15 c.c./min. and the zero apparent initial retention time corresponded to 22·0 min. It was recognized with a detector tube method[6] that the formic acid partly remained unreacted while it passed through the catalyst column at 99° C. and a sharp peak of the acid slug was observed when it was injected as a sample.

Table 1

Carrier gases	Samples	Apparent initial retention time (min.)
Nitrogen	Argon	0
Nitrogen	Carbon dioxide	0
Nitrogen	Hydrogen	8·5
Hydrogen	Nitrogen	0
Hydrogen	Formic acid	0
Nitrogen saturated with formic acid at 20° C.	Carbon dioxide	0
	Hydrogen	8·0

The experimental results shown in Table 1 suggest that both carbon dioxide and formic acid could scarcely be adsorbed on the catalyst surface and only hydrogen could be adsorbed almost in adsorption equilibrium.

The reaction was also studied in a closed circulating system. It is shown by this experiment and also by Topley and Hinshelwood[7] that the decomposition of formic acid on palladium is first order in formic acid and slightly retarded by hydrogen, being independent of carbon dioxide pressure.

If the adsorption on the whole surface is assumed to be similar to that on the active part, it seems reasonable to suppose from all of these results that the rate-controlling step in the formic acid decomposition would be the chemisorption of the acid on to the catalyst surface. The chemisorption rate of the acid on the catalyst surface is proportional to the partial pressure of the acid, while the sites available for the chemisorption is decreased by the increasing hydrogen adsorption as hydrogen pressure becomes higher, thus showing the retardation by hydrogen.

The reason why the apparent initial retention time of hydrogen is shorter during the decomposition than with inert carrier gas is supposedly due to the hydrogen produced by the decomposition decreasing the apparent adsorbability to hydrogen.

It has been shown thus far that we can study adsorption during surface catalysis with the gas chromatographic technique. Another example to be treated with this new approach is to study the adsorption of decomposing (or polymerizing) reactant on the catalyst. Suppose a decomposition (or polymerization) reaction of *A*, and that *A* is weakly adsorbed on the catalyst almost in adsorption equilibrium and the surface reaction is rate-determining. Using similar apparatus to that mentioned above, and with an inert carrier gas, the reactant is injected at the top of the adsorption column filled with catalyst. From the retention time of the remaining reactant at various temperatures, its heat of adsorption would be estimated.

Generally speaking, it is difficult to estimate the heat of adsorption of a decomposing (or polymerizing) reactant except from the adsorption measurements during catalysis as has previously been reported in the decomposition of formic acid on a silver catalyst[8], as neither the calorimetric method nor the isosteric heat method can be applied, since decomposition takes place simultaneously. The new method, however, will enable us to determine such heats of adsorption.

This work was carried out with financial support from Ashai Chemical Industry Promoting Foundation, Inc., Tokyo, and also from the Ministry of Education, to which my thanks are due. The assistance of Mr. H. Miyake is gratefully acknowledged. I also wish to thank Dr. R. Amemiya for helpful discussions.

Polarography of Aromatic Hydrocarbons

HALF-WAVE potentials of aromatic hydrocarbons have been plotted graphically against calculated energies of the lowest unoccupied molecular orbitals, localization energies of one or two positions in the molecule and spectroscopic data[1–6]. Various linear relationships were discovered during these attempts to correlate reduction potential with some fundamental quantity related to molecular structure.

In his contribution[6] Given stated that those authors who compared half-wave potential with the localization energy of two positions in the molecule did not understand properly the polarographic evidence[4,7–11], which he believed to indicate that only one electron was added in the potential-determining stage of reduction.

While a two-electron reduction, which aromatic hydrocarbons undergo, may proceed perhaps in two one-electron stages a strong argument can be made that the potential-determining stage encompasses the addition of two electrons. In view of such an argument, which follows here, is it wise to discourage comparisons of half-wave potential with appropriate quantities related to two-electron addition ?

Inspection of the plots of E versus $\log_{10} i/(i_d - i)$ for the polarographic waves of aromatic hydrocarbons dissolved in a variety of solvent mixtures[4,7-11] shows that near linearity exists. The polarographic waves are therefore described by the Kolthoff–Lingane[12] empirical equation:

$$E = E_{1/2} - (2 \cdot 303\, RT/\alpha\, nF) \log_{10} i/(i_d - i) \quad (1)$$

where E is the cathode potential, $E_{1/2}$ the half-wave potential, R the gas constant, T the absolute temperature, F Faraday's constant, i the current, i_d the limiting current, n the number of electrons calculated directly from the magnitude of i_d and α a parameter. For the aromatic hydrocarbons $n = 2$ and α is usually less than 0·5.

In the example of the aromatic hydrocarbons, a possible reaction sequence for the aqueous polarographic reduction of the C═C bond is:

$$\mathrm{C{=}C} + 2e \overset{k_1}{\rightleftharpoons} \bar{\mathrm{C}}\mathrm{—}\bar{\mathrm{C}} \xrightarrow[\mathrm{H_2O}]{k} \mathrm{CH—}\bar{\mathrm{C}} \xrightarrow[\mathrm{H_2O}]{} \mathrm{CH—CH} \quad (2)$$

The rapid and irreversible conversion of the dianion into the saturated hydrocarbon removes the dianion from prolonged electrode equilibrium with the unsaturated hydrocarbon. (Such dianions are only stable in the absence of proton donors[13,14].) An equation (3) relevant to the sequence (2) may be derived using the methods described in ref. 15 for an electron uptake succeeded by a rapid reaction:

$$-E = (RT/\alpha\, nF) \log_e 1 \cdot 23\, D^{1/2} t^{-1/2} \mu^{-1} k^{-1} + (RT/\alpha\, nF) \log_e i/(i_d - i) \quad (3)$$

where D is the diffusion coefficient of the unsaturated hydrocarbon, t the drop time, μ the reaction layer thickness, k_1 the rate constant for electron uptake and α is interpreted now as the fraction of potential which assists the forward reaction.

Equation (3) is seen to be similar in form to equation (1) so far as the variables E, i, n and α are concerned. The term $(RT/\alpha\, nF) \log_e 1 \cdot 23\, D^{1/2} t^{-1/2} \mu^{-1} k^{-1}$ is constant for a given medium, temperature and drop time, and therefore may replace $E_{1/2}$ in equation (1). Complete verification awaits experimental determination of μ and k_1.

The similarity of equation (3) to the empirical equation for the polarographic waves of aromatic hydrocarbons (equation 1) shows that their polarographic reduction is described adequately by a mechanism the potential-determining stage of which is due to uptake of two electrons.

BIOCHEMISTRY and PHYSIOLOGY

An Electron Spin Resonance Study of the State of Copper in Fungal Laccase

The work of Keilin and Mann[1] and of Tissières[2] conclusively demonstrated that laccase is a copper-protein enzyme. By analogy with the suggestion of Kubowitz[3] in regard to polyphenoloxidase, it has generally been assumed that the enzyme contains Cu (II) in the resting state, and that catalytic activity is associated with a change in valency of the metal to Cu (I) (see, for example, ref. 4); but a direct study of this problem has never been made. Kertész[5] has recently pointed out that Kubowitz's indirect method may give erroneous results, and he has, in fact, presented evidence that the metal in mushroom polyphenoloxidase is always in the Cu (I) state. The recent development of the electron spin resonance technique has made possible a more direct approach to this problem, and in the present communication we would like to present results of this technique which clearly show that fungal laccase contains Cu (II) which, during the oxidation of substrate, changes valency to Cu (I).

The fungal laccase used for this investigation was obtained as an induced exoenzyme of *Polyporus versicolor*; it was purified by a procedure recently described[6]. On a protein basis, the purified enzyme contains 0·4 per cent copper[6]. It is deep blue in colour with an absorption maximum at 615 mμ. However, the crude enzyme is often green, in which cases pigment with an absorption maximum at 405 mμ can be removed by various methods, for example, chromatography on 'Dowex 2' or on calcium phosphate (R. Mosbach, unpublished experiments). No way has been found to dissociate the blue colour from the enzyme.

For the measurements of electron spin resonance, 0·2 ml. of an approximately 2 per cent laccase solution in deionized water (pH about 5) was used. The samples were contained in quartz tubes having inside and outside diameters of about 3 and 4·5 mm., respectively. Substrates and other substances tested were added as solids, and the solutions were quickly frozen in liquid air. No attempt was made to exclude oxygen from the solutions. The electron spin resonance spectra were recorded with the frozen solutions at approximately 100° K. with a 3-cm. Varian *V*-4500 spectrometer.

Typical electron spin resonance absorption curves under a number of experimental conditions are given in Fig. 1. The blank in Fig. 1*a* shows that the quartz tubes and solvent used are essentially free of contaminating copper, while the strong resonance line shown in Fig. 1*b* demonstrates that the enzyme contains Cu (II) in the resting state, since Cu (I) is not paramagnetic and, consequently, would give no electron spin resonance signal. The absorption curve is asymmetric, probably due to an anisotropic g-factor. The g-value at maximum absorption, which should be close to $g_\perp$, is $2 \cdot 06 \pm 0 \cdot 01$; other covalent Cu (II) complexes have been found to have similar g-values[7]. The small peaks to the left of the centre seem to be associated with the copper resonance, since they disappear on reduction (Fig. 1*c*), and they probably originate from an anisotropic hyperfine structure. It is hoped that a detailed study of simpler Cu (II) complexes (mainly with amino-acids and peptides) now in progress may yield information

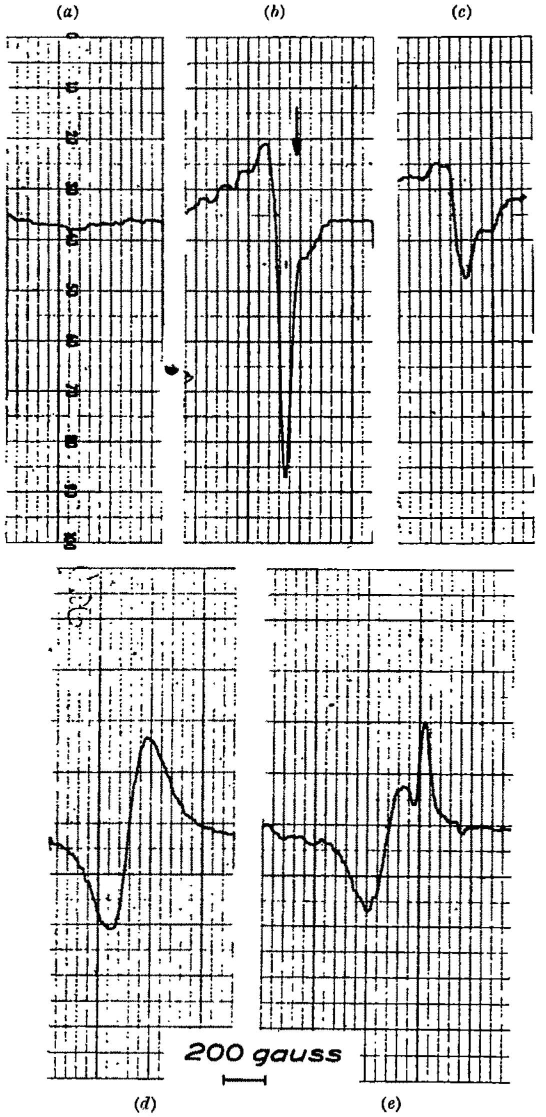

Fig. 1. Derivatives of electron spin resonance absorption curves recorded at about 100° K. Samples: (*a*) blank (deionized water); (*b*) about 2 per cent laccase solution; (*c*) about 2 per cent laccase solution plus excess catechol; (*d*) 1·5 × 10^{-3} *M* copper sulphate; (*e*) 1·5 × 10^{-3} *M* copper sulphate plus catechol. The arrow in (*b*) indicates the resonance field for free electrons

permitting a more exact interpretation of the laccase spectrum.

The absorption curve shown in Fig. 1*c* was recorded after a substrate (catechol) had been added to the enzyme solution used for Fig. 1*b*. The presence of substrate is seen greatly to diminish the electron spin resonance signal, showing that much of the metal has been reduced to Cu (I). Whether the remaining signal represents the steady-state concentration of oxidized enzyme, or is due to copper that is not associated with the activity of the enzyme, cannot be decided at present, since no experiments in the absence of oxygen have been performed. Other substrates, for example, ascorbic acid, cause a similar reduction in the resonance line, while, for example, tyrosine (a substrate of polyphenoloxidase) has no effect. When the substrate has been exhausted, the resonance reappears completely. It may be of interest to note that the blue colour disappears and reappears at the same time as the Cu (II) resonance line, though this does not necessarily mean that the colour is due to the metal ion (cf. refs. 8 and 9).

The spectra shown in Figs. 1*d* and 1*e* are included to demonstrate that the observed reduction in the resonance line cannot be due simply to complex formation with the substrate. Fig. 1*d* shows the absorption curve obtained with a solution of copper sulphate, and Fig. 1*e* that of the same solution after addition of catechol. It can be seen that, though the presence of substrate changes the shape of the absorption curve, it has no effect on the intensity of the signal.

The results reported here indicate that while Kubowitz's hypothesis[3] may not be valid for the enzyme for which it was formulated[5], it does appear to explain the role of the metal in laccase action. However, until more extensive experiments, in conjunction with kinetic measurements, have been performed, it is not possible unequivocally to relate the observed changes with the catalytic action of the enzyme. We hope to publish a more detailed report later.

This investigation has been supported by the Swedish Natural Science Research Council and the Rockefeller Foundation. We wish to thank Profs. A. Tiselius and K. Siegbahn for stimulating interest, and Dr. G. Fåhraeus for supplying the crude laccase from fungal cultures.

Reaction of Sodium Borohydride with Wool

Recent developments[1-4] in the fractional extraction of wool proteins followed by their purification and physico-chemical characterization have led to a better understanding of the molecular structure of the fibre. But so far less than 50 per cent of the fibre has been separated into single proteins, and further work needs to be done in this field. A difficulty has been the lack of ideal methods for dissolving wool, for all those in current use suffer from one or more disadvantages, such as the side-reactions associated with the peracetic acid–ammonia procedure or the comparatively drastic conditions of *p*H and temperature often used with thioglycollate.

It has recently been found that sodium borohydride in alkaline solution rapidly dissolves wool under conditions of temperature and *p*H milder than many in current use. The reaction has been studied as follows: 1 gm. of solvent-scoured Merino wool was thoroughly wetted with 100 ml. of sodium borohydride solution, agitated at intervals and at the end of the reaction the residue filtered on to tared Whatman 54 filter paper, washed once with distilled water and dried at 105° C. to constant weight. The effects of

Table 1. EFFECT OF CONCENTRATION AND TEMPERATURE ON THE EXTRACTION OF WOOL PROTEIN BY SODIUM BOROHYDRIDE

Sodium borohydride concentration (*M*)	Urea concentration (*M*)	*p*H		Temperature (° C.)	Time (hr.)	Wool dissolved (per cent)
		Start	Finish			
0·1	0	11·0	10·6	40	1	89
1·0	0	11·0	10·6	1	12	60
1·0	0	10·2	10·3	1	12	71
1·0	0	11·0	10·6	20	1	92
1·0	6	10·9	10·6	1	12	87
1·0	6	10·9	10·6	20	1	91

variation in reagent composition and reaction temperature on the extent of wool solution are shown in Table 1.

The influence of *p*H on the reaction was next studied; but was difficult to measure because of the buffering effect of the metaborate end-product and the increase in the decomposition rate of the sodium borohydride as the *p*H was lowered. However, some experimental results (Table 2) with 1·0 *M* sodium borohydride solutions at 1·0° C. suggest that wool was dissolved optimally at initial *p*H values in the range 10–11.

Table 2. EFFECT OF INITIAL *p*H ON THE EXTRACTION OF WOOL PROTEIN BY SODIUM BOROHYDRIDE AT 1·0° C. FOR 12 HR.

Initial *p*H	Final *p*H	Wool dissolved (per cent)
9·1	10·5	35
10·2	10·3	71
11·0	10·5	52
11·8	11·5	7

The S-carboxymethyl derivative of the soluble protein was prepared by adjusting the *p*H of a digest solution (equivalent to 92 per cent of wool) to *p*H 8·5, a very slight excess over the theoretical amount of sodium iodoacetate was then added and the *p*H maintained at 8·5 for 15 min. The solution was then dialysed against running distilled water in a cellulose sausage casing with one end open to allow hydrogen to escape. The protein was then fractionated[2] on the basis of solubility at *p*H 4·5, the major part being insoluble under these conditions. Ultracentrifuge runs made on the *p*H 4·5 insoluble fraction, in 0·2 *M* potassium chloride at *p*H 7, showed the presence of at least 2 components (Fig. 1) of $S_{20\,w}$ 1·7 and 3·5 respectively, at a protein concentration of 1 per cent. Electrophoresis at *p*H 11 in 0·1 ionic strength buffer gave one spread-out peak in both boundaries.

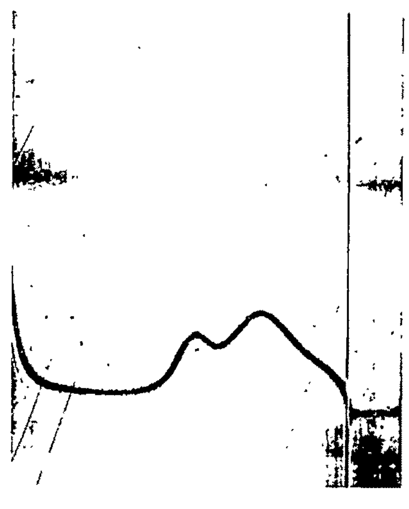

Fig. 1. Ultracentrifuge pattern of extracted wool protein (S-carboxymethyl derivative)

It is planned to study further the proteins in these extracts and in particular those more difficultly extractable materials which are largely undissolved by treatment of wool with alkaline thioglycollate solutions.

Preparation of Ceruloplasmin

CERULOPLASMIN is one of the minor components of plasma proteins. Most of the numerous publications which have appeared in the past several years are concerned with the evaluation and clinical significance of hypo- and hyper-ceruloplasminæmia. Nevertheless, the biological role of ceruloplasmin is still unknown.

Clinical and laboratory research might be facilitated if ceruloplasmin could be available in sufficient quantities.

Ceruloplasmin was first isolated by Holmberg and Laurell[1] using a technique based on the precipitation of globulins by 50 per cent saturation with ammonium sulphate and subsequent denaturation of the accompanying proteins by repeated treatment with a mixture of alcohol and chloroform.

As normal plasma contains but 150–300 mgm./l. of ceruloplasmin, it would be necessary to combine the preparation of suitable quantities of ceruloplasmin with one of the routine fractionation techniques.

The handling of Holmberg and Laurell's alcohol–chloroform mixture is rather inconvenient for the technical preparation of ceruloplasmin. So, we investigated other methods allowing the subfractionation of fractions containing ceruloplasmin.

Rivanol, an acridine derivative, has been used for preparing γ-globulin[2] and more recently for the isolation of β_1-metal-combining globulin[3]. Neither γ-globulin nor β_1-metal-combining protein is precipitated by rivanol, and these proteins are separated by alcohol precipitation of the supernatant. We think that rivanol might be used as a more general separating agent if it should be possible to dissociate the rivanol–protein complex without damaging the protein. Ceruloplasmin is particularly indicated for such a study as this protein exhibits oxidase activity allowing an easy control of each step of the separation technique.

Ceruloplasmin has a strong tendency to interact with other proteins, and under the conditions of our routine work we find the copper-protein in fraction III and IV. We have succeeded in isolating ceruloplasmin of both these fractions by subfractionation with rivanol. The method is based on the following principles: (1) Precipitation by rivanol of some accompanying globulins at *p*H 6. No oxidase activity should be detected in this precipitate. (2) Adjustment of *p*H to 7·8, and addition of another portion of diamino-ethoxyacridine-lactate in order to precipitate the fraction containing ceruloplasmin. Final *p*H should be 7·3–7·5. No oxidase activity should remain in the supernatant liquid. The latter might be used for preparing the β_1-metal-combining globulin in the case of fraction IV as starting material. (3) The rivanol–protein complex of step 2 is dissociated at *p*H 4; the accompanying proteins are eliminated by treatment with 50 per cent alcohol at *p*H 4·0. (4) The precipitate is extracted at *p*H 6. If further purification is necessary, it can be precipitated once more at *p*H 5·9, and 25 per cent alcohol concentration; it is then clarified before lyophilization.

Influence of Ions on the Uptake of Glucose and on the Effect of Insulin on it by Rat Diaphragm

INSULIN causes an increased uptake of glucose by the rat diaphragm *in vitro*[1]. The present communication reports the results of some experiments designed to study the influence of physiologically important cations on the uptake of glucose by the diaphragm of the rat in the presence and absence of insulin. Incidentally, the effects of the other related monovalent metallic ions and of changes in gas phase were also studied.

The incubation mixture consisted of a suitable buffer in isotonic sucrose or in a mixture of isotonic sucrose and isotonic solutions of the chlorides of certain mono- and di-valent metals. In every instance the *p*H of the medium was adjusted to 7·4 and glucose added to make a final concentration of about 250 mgm./100 ml. The buffers used, and their concentrations in the medium, were as follows: lithium, sodium and potassium bicarbonates, 0·02 *M*, disodium hydrogen phosphate, 0·01 *M*, *tris*aminomethane, 0·025 *M*. One hemidiaphragm was suspended in 1 ml. of the medium containing, where indicated, 100 milliunits of insulin per ml. The incubation was carried out at 38° C. for 90 min.

The results given in Table 1 show that diaphragm incubated in isotonic sucrose containing no metallic ion (*tris* buffer) or only small amounts of them (bicarbonate or phosphate buffer) removed glucose from the medium in amounts comparable to those removed from Gey and Gey's salt mixture. Insulin, however, had little or no effect on the uptake of glucose under such conditions. The ability of the tissue to respond to insulin appeared only when rather high concentrations of metallic ions such as sodium, potassium, rubidium, cæsium and magnesium were present in the medium. There was, however, little or no response to insulin in the presence of varying amounts of lithium or calcium.

The poorness of the response to insulin in media containing lithium ions apparently resulted from the high basal uptake of glucose from such media. On the other hand, the absence of any insulin response in the presence of calcium ions was possibly due to their toxic effects, as evidenced by the very low basal uptake of glucose in the presence of calcium ions. In both cases, the basal uptake of glucose could be adjusted to about the normal level by reducing the amounts of lithium or calcium ions added; but then again there was little or no response to insulin, presumably because the concentrations of the essential ions in the media were too low.

Table 1. EFFECT OF METALLIC IONS ON THE INFLUENCE OF INSULIN IN CAUSING INCREASED UPTAKE OF GLUCOSE BY RAT DIAPHRAGM UNDER AEROBIC CONDITION

Medium	Buffer	Glucose uptake (mgm./hr./gm. of tissue) Without insulin	With insulin (100 milliunits/ml.)	*P*

† Not significant.

It has already been noted that the basal uptake of glucose in the presence of lithium ions was high. In fact, the uptake differed in a regular way in the presence of equivalent amounts of the different metallic ions in the medium. A comparison of the uptake of glucose by the diaphragm in the presence of equivalent amounts of the monovalent metallic ions in the medium is given in Table 2. It is seen that the uptake followed the order of lithium > sodium > potassium = rubidium > cæsium. It is interesting to note that this is the order of the above ions in the so-called lyotropic or Hofmeister series.

The experiments so far reported were all carried out under aerobic condition. The results of a few similar experiments carried out under anaerobic condition are given in Table 3. The results show

Table 2. COMPARISON OF GLUCOSE UPTAKE BY RAT DIAPHRAGM INCUBATED IN MEDIA CONTAINING EQUIVALENT AMOUNTS OF THE MONOVALENT METALLIC IONS

Experiment No.	Composition of medium	Buffer	Glucose uptake	*P*
1	Sucrose–LiCl (1 : 1) Sucrose–NaCl (1 : 1)	Bicarbonate	7·48±0·26* 5·83±0·43	<0·05†

that under anaerobiosis there was little response to insulin even when the medium contained the required ions in sufficient amounts. It may, however, be noted that with bicarbonate buffer the basal uptake of glucose tended to be higher under anaerobic conditions than under aerobic conditions. This was particularly true for sucrose–sodium chloride medium. These observations agree with those on the effect of anaerobiosis in increasing the basal uptake of glucose by rat diaphragm from Gey and Gey's salt mixture previously reported by Randle[2] from this laboratory.

From a consideration of the foregoing results one wonders whether there are two separate and distinct processes (one, insulin-independent and the other, insulin-dependent) involved in the uptake of glucose by the diaphragm of the rat. The process independent of insulin, although markedly influenced by strong ionic environments, can, nevertheless, function in a more or less normal way in the absence of metallic ions in the added medium. It can also function both under aerobic and anaerobic conditions. The process dependent on insulin, however, seems to operate best under aerobic condition and in the presence of rather high concentrations of certain metallic ions, including the physiologically important ions of sodium, potassium and magnesium. Ions of sodium and potassium are actually present in large amounts in the extracellular and intracellular fluids, respectively. The results reported here may thus have some physiological significance with respect to insulin action in the whole animal. They may also throw some light on the now generally accepted glucose-transport theory of insulin action[3].

The effect of the chloride ion, which was present in the medium in large amounts in most of the experiments reported here, has not been considered specifically. A general consideration of the results, however, indicates that most probably the chloride ion was not responsible for the effects of the added salts.

I am indebted to Prof. F. G. Young for advice and criticism and for the grant of laboratory facilities. My thanks are due to the managers of the I.C.I. Fellowships Fund, University of Cambridge, for the grant of a fellowship. The sample of crystalline insulin used in the above experiments was kindly given by Dr. C. G. Pope of the Wellcome Foundation, London.

Immunochemically Active Cross-linked Polystyrene

THE communication of Gyenes, Rose and Sehon[1] prompts us to record briefly some observations in a closely related field.

For some time a group of our colleagues has been investigating the separation of antigens by means of their immunochemical specificity[2]. They have, for example, attempted to invert the method used by Campbell[3] and others for the fractionation of antibodies, and, by chemically conjugating antibody protein to a polymer such as cellulose, have used the resulting product in a column to separate antigens. The amount of antibody protein which can be incorporated in this manner is not large, and as a result of the generally unfavourable stoichiometry in respect to the antigen in the immune reaction, the capacity for the antigen is quite low. It occurred to us that greater capacity could be achieved if the antibody protein could be made an integral part of the three-dimensional structure, and we proceeded independently on lines precisely similar to those of Gyenes, Rose and Sehon.

'Distrene', an essentially linear polymer of styrene, was nitrated, initially with fuming nitric acid/sulphuric acid to give a product containing approximately 1 nitro group per styrene residue, and the product reduced with a large excess of stannous chloride to the polyamino compound[4]. This was soluble in dilute mineral acid but insoluble in dilute alkali. On diazotization in acid solution it gave, surprisingly, a very sparingly soluble diazonium salt. The γ-globulin fractions (which are rich in antibody) from several immune sera, prepared against a partially purified protein fraction from *Pasteurella pestis* (rabbit), against *B. anthracis* (horse) and an anti-ovalbumin serum (rabbit) were prepared by sodium sulphate precipitation[5]. The suspension of the polydiazonium styrene was then coupled with the immune γ-globulin in phosphate buffer at *p*H 8·5 and the excess unreacted diazonium groups rendered unreactive by coupling with resorcinol. The resulting cross-linked polymers were washed thoroughly with buffer until the filtrates were free from protein and were stored in isotonic saline. They contained 20–30 per cent of their weight of firmly bound protein. In view of the insolubility in water of the polydiazonium styrene, it was more closely examined and found to contain a small percentage of sulphonic acid groups, derived presumably from the sulphuric acid used in the nitrating process. When this was omitted, the product after reduction gave a completely soluble diazonium salt which would conjugate with much more γ-globulin. After treatment as above, the final polymer contained 60–70 per cent of its weight of protein. The products, though softer than the normal cross-linked polystyrene resins, are easily handled and readily filterable.

These 'resins' show approximately the capacity for absorbing their respective antigens that would be expected from the neutralizing capacity of the anti-sera from which they are prepared. They do this in all cases with a marked degree of specificity. In some cases the specificity is high. Thus, a 'resin' prepared from an anti-anthrax serum removed the protective antigen quantitatively from a culture filtrate prepared by the method of Thorne and Belton[6] without significant reduction in the total protein content of the filtrate. A 'resin' prepared from an anti-ovalbumin serum failed to remove bovine serum albumin from buffer solution but quantitatively removed ovalbumin under the same conditions: that from the plague anti-serum, though it removed the toxin quantitatively under all conditions tested, also removed some other protein. As several other antigens are present in the protein fraction used as antigen and the anti-serum contains antibodies to several constituents of the plague organism, this is not surprising.

The preparations were subject to a more stringent test for specificity by comparing their behaviour with precisely similar 'resins' prepared from normal γ-globulin. In the case of the anti-ovalbumin 'resin', the same high specificity was shown. Under the same conditions that the anti-ovalbumin 'resin' removed ovalbumin quantitatively from solution the resin prepared from normal rabbit γ-globulin removed none. The latter 'resin' did, however, remove some protein from the protein fraction from *P. pestis* and, despite a number of attempts, we have not succeeded in reducing this non-specific absorption below 15–25 per cent in this case.

We have also succeeded in preparing cross-linked resins by direct mercuration of polystyrene and cross-linking the polymer chains via the sulphydryl group of the antibody protein. Their immunochemical properties are exactly similar to those of the diazo 'resins'. Anthrax antigen absorbed on the anti-anthrax 'resin' when injected into rabbits and guinea pigs confers active immunity, and the animals will survive the challenge of a lethal dose of anthrax organisms. This indicates that the antigen retains its biological activity when absorbed.

Full details of this work will be published elsewhere.

We are indebted to Dr. D. A. L. Davies and Dr. A. P. MacLennan for toxicity tests in mice and to Mr. F. C. Belton for immunological assays of the anti-anthrax preparations.

Evidence for the Conversion of Quinic Acid to Shikimic Acid in Roses

The simultaneous occurrence of quinic and shikimic acids has been reported in several plants[1–3]. No definite role has been ascribed to either of these alicyclic acids in higher plants, except for participation of the former in the synthesis of chlorogenic acid[4].

In certain micro-organisms, shikimic acid has been demonstrated to be in the direct path to aromatic ring biosynthesis[5]. Microbial response to exogenous quinic acid has been reported in secondary mutants of *Aerobacter* which grew well when supplied with quinic acid[5]. Similar results have been reported for a mutant of *Neurospora*. A quinic dehydrogenase, which converts quinic acid to 5-dehydroquinic acid, has been demonstrated in *Aerobacter*[5], although the enzyme is not widely distributed. Davis[5] has concluded that quinic acid is not directly involved in aromatic ring biosynthesis in micro-organisms, and that where a requirement has been shown to exist, it is due to an adventitious quinic dehydrogenase.

The recent discovery of a high concentration of quinic acid in rose tissues[6] suggested the use of this plant for the biosynthesis of quinic acid labelled with carbon-14. This was accomplished by exposing actively growing plants of the variety 'Redbird' to $^{14}CO_2$ in light. Quinic acid labelled with carbon-14 was isolated by ion-exchange chromatography and crystallized. The labelled acid was fed into young blooms of 'Better Times' roses through cut stems and allowed to metabolize for 5, 23, 45 and 71 hr. before harvesting. The blooms were fractionated and radioactivity was determined in each of the non-volatile organic acids, free amino-acids, sugars and protein amino-acids.

More than 25 per cent of the carbon-14 in quinic acid fed to the roses could not be accounted for in any fraction and was presumably metabolized and lost as $^{14}CO_2$. This was confirmed in a subsequent experiment, where it was found that about 20 per cent of the radioactivity was evolved as $^{14}CO_2$ in 71 hr.

In petals, approximately 10 per cent of the incorporated carbon-14 could be accounted for in other compounds, and the remainder was present as quinic acid. About 25 per cent of the carbon-14 appearing in non-volatile organic acids was recovered as labelled shikimic acid. In petals of roses harvested after 71 hr., about 20 per cent of the carbon-14 in free amino-acids appeared in tyrosine and about 20 per cent appeared in phenylalanine.

The results show that quinic acid is metabolized by roses. This is borne out by other results indicating that quinic acid normally increases in concentration in rose blooms until they become about half open, after which the concentration decreases[7]. A similar development has been observed in apple fruits[2]. The evidence is clear that roses contain the enzymes necessary to reduce quinic to shikimic acid, although no evidence can be presented as to whether or not it follows the classical mechanism via quinic dehydrogenase, 5-dehydroquinase, and 5-dehydroshikimic reductase[5]. The possibility that the label in shikimic acid could arise from decarboxylation of quinic acid and its subsequent incorporation via a dark fixation mechanism has been ruled out since earlier experiments have shown no label to be incorporated into the quinic–shikimic fraction during dark fixation of $^{14}CO_2$.

Co-existence of the Embryonic (Third Normal) Hæmoglobin Fraction with Erythroblastosis in the Blood of Two Full-term New-born Babies with Multiple Malformations

In previous communications[1,2] the existence of a third normal, embryonic hæmoglobin was reported to be present in the blood of fœtuses up to five months of intra-uterine life. The hæmolysates of the blood of these fœtuses were characterized by their electrophoretic mobility on filter paper in a buffer solution of pH 8·6, which was slower than that shown by the hæmolysates obtained from the cord blood of full-term new-borns. The paper electrophoresis method did not permit us, however, to separate the different hæmoglobin fractions present either in the fœtal or in the embryonic blood.

By using the column chromatographic procedure described by Huisman and Prins[3], with some minor modifications, we were able to separate the three distinct fractions from the hæmolysate of a four month old embryo weighing 90 gm.

The hæmolysates of the cord blood of full-term new-born babies which were used at the same time as controls showed only two fractions (Fig. 1). The purpose of this communication is to report the finding of the third (embryonic) hæmoglobin fraction in the blood of two full-term new-born babies with multiple congenital malformations.

A further interesting and unusual feature of the blood of these new-borns was an erythroblastosis which was found in the blood film and which could not be explained by a blood group incompatibility between mothers and infants.

One baby weighing 2,560 gm. was born to a healthy 28-year-old primipara and showed the following congenital malformations: 1, multiple defects of the scalp; 2, hare lip; 3, polydactyly of both hands; 4, cryptorchism.

Mother and infant had identical blood groups (A CDe/CDe). No hepatosplenomegaly was found. In the blood film an unusually large number of nucleated red cells in all stages of maturation was found, but their absolute number was not determined. 1 hr. after birth the infant died. The hæmolysate of the cord blood of this malformed infant was found to contain 66·9 per cent of the alkali-resistant type of hæmoglobin. Paper electrophoresis did not reveal the presence of embryonic hæmoglobin, whereas the column chromatographic method, using an 'Amberlite *ICR* 50' column and a citrate buffer solution of pH 6·0 with a sodium ion concentration of 0·15 as an eluting solvent at a rate of flow of 9 ml. per hr., did reveal the three distinct hæmoglobin fractions similar to those shown in Fig. 1.

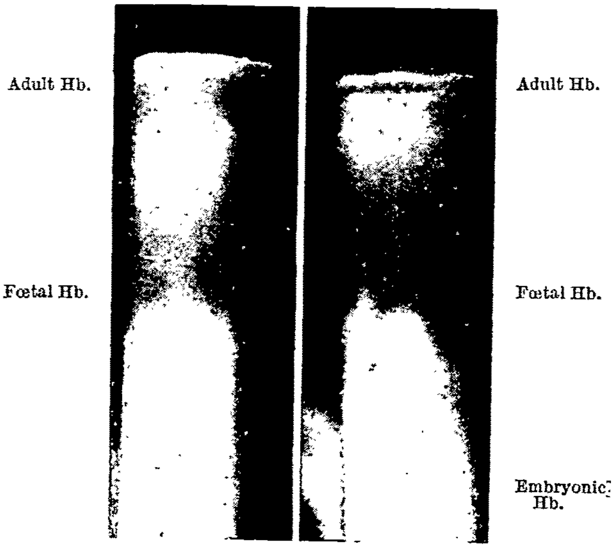

Fig. 1. 'Amberlite' column chromatography of (left) the hæmolysate of the cord blood of a full-term new-born showing two hæmoglobin fractions (adult and fœtal) and (right) of the hæmolysate of a four-months-old embryo showing three hæmoglobin fractions (adult, fœtal and embryonic)

Another baby was born to a healthy mother of two healthy children. The malformations of this child consisted of: 1, fusion of the two nasal fossa into one cavity; 2, under-development of the external genital organs of male type; 3, absence of the gonads in the very small scrotum and in both inguinal canals. The infant died shortly after birth, and section revealed the presence of a uterus and of two gonads, which on histological examination proved to be ovaries. The blood groups of both parents and of the child were identical (O cDe/cDe). The blood count of the baby's peripheral blood showed: hæmoglobin 18·2 gm./100 ml.; red blood count 6·4 millions/cu. mm.; white blood count 25,000/cu. mm. Examination of the blood film showed: nucleated erythrocytes, 45/100 white blood count. The direct and indirect Coombs tests were negative. The hæmolysate of the cord blood of this baby contained 73·3 per cent of the alkali-resistant hæmoglobin fraction, and column chromatographic examination revealed three distinct hæmoglobin fractions.

The use of the 'Amberlite' column chromatographic procedure represents an important step forward in the separation of the different fractions of normal hæmoglobin. Thus, we were able to separate not only the two hæmoglobin fractions known to be present in the cord blood of full-term new-borns, but also the third, embryonic, fraction (the lowest in the chromatographic column) in the blood of small embryos.

The interest of the present observation lies in the fact that by using the column chromatographic method we were, for the first time, able to discover the embryonic hæmoglobin fraction in the blood of two full-term new-borns who were severely malformed, whereas twenty other normal new-borns who served as controls did not show this fraction in their blood.

Another interesting fact lies in the co-existence of the embryonic hæmoglobin fraction with erythroblastosis in the blood of these malformed infants.

Erythroblastosis fœtalis has hitherto been found either associated with blood-group incompatibilities of the Rh and ABO systems or occasionally in the blood of prematures or of infants born to diabetic mothers. So far, we are unaware of reports on erythroblastosis in the blood of full-term new-borns with congenital malformations, in the absence of the above-mentioned conditions.

It is generally admitted that the synthesis of the normal, as well as of the abnormal, hæmoglobins is genetically determined, and so is the physiological process of replacement of the fœtal by the adult type of hæmoglobin which starts very early in embryonic life and continues until its completion between the sixth and the twenty-fourth month after birth.

It seems equally probable that the synthesis of the embryonic hæmoglobin as well as its replacement by the later (fœtal and adult) hæmoglobins are determined by genetic factors. The persistence of the embryonic hæmoglobin in the blood of the two above-described malformed new-borns could therefore be explained by a disturbance of one or more genetic factors which leads to the appearance of multiple developmental mutations, one of them being the persistence of embryonic hæmoglobin.

The association of persistent embryonic hæmoglobin with erythroblastosis in the blood of the new-borns is another phenomenon which remains to be explained by further investigations.

Pharmacological Actions of γ-Butyrobetaine

γ-Butyrobetaine is a substance which has been known for many years to be present in the tissues of some cold-blooded animals, for example, snakes (*Python*)[1] and freshwater eels[2]. It appears, however, not to be present normally in mammalian tissues, but it has been located in muscle extract[3] and decaying horse flesh[4], and may appear in the urine in phosphorous poisoning[5] or in pernicious anæmia[6]. Linneweh[7] has shown that γ-butyrobetaine injected into dogs is largely excreted unchanged, although a small proportion is oxidized to carnitine.

Recently, Hosein[8] has shown that γ-butyrobetaine can be identified in the brains of mammals in which convulsions have been induced by the intraperitoneal injection of the so-called cerebral convulsants, while it is never found in this form in the brains of normal animals. Other studies by Hosein[8] have revealed that in normal animals γ-butyrobetaine occurs as a complex with coenzyme *A*. The pharmacological actions of γ-butyrobetaine, after subcutaneous administration into mice, were reported by Linneweh[7]. He found that there was increased respiration, profuse salivation and lacrymation, dilatation of the pupils, vasoconstriction, voiding of urine and fæces, block of motor nerve endings and cardiac arrest in diastole. A fatal dose of γ-butyrobetaine as the chloride was 70–80 mgm. in a 15-gm. mouse. From these observations Linneweh concluded that γ-butyrobetaine behaved as a curare-like substance.

In the light of Hosein's findings, we have felt it desirable to investigate again some of the pharmacological actions of this substance. γ-Butyrobetaine was prepared synthetically as the free base and used for all tests. Subcutaneous injection of as little as 1 mgm. was found to be fatal to a 25-gm. mouse, and the sequence of events described by Linneweh[7] was invariably observed. There is evidently a profound autonomic excitation which culminates in death apparently due to cardiac failure.

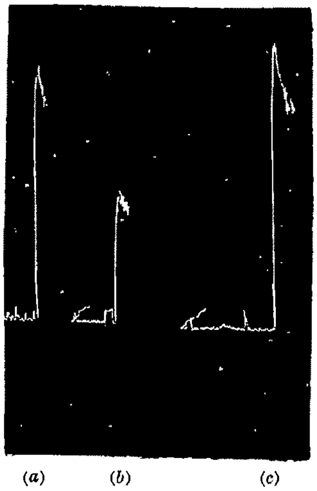

Fig. 1. The effect of acetylcholine and factor I on the isolated ileum of the guinea pig. (*a*) Acetylcholine, 1·2 × 10^{-9}; (*b*) acetylcholine, 1·2 × 10^{-9} + factor I, 0·003 units/ml. of bath fluid; (*c*) acetylcholine, 1·2 × 10^{-9}

In its actions γ-butyrobetaine resembles those of acetylcholine except that it is much less active on a weight-for-weight basis and its action is considerably prolonged. It seems not to be enzymatically destroyed in the body at any appreciable rate, as Linneweh's experiments on its recovery from urine showed. We have observed a parallelism in action between γ-butyrobetaine and acetylcholine for depression of the blood pressure of the cat, stimulation of the perfused superior cervical ganglion in the cat, and inhibition of the isolated perfused frog heart. Inhibition of mammalian neuromuscular transmission, similar to that caused by large doses of acetylcholine[9], is invariably found.

In only one preparation has it been possible to show a qualitative difference in action between γ-butyrobetaine and acetylcholine. The isolated ileum of the guinea pig is induced to contract by the addition of γ-butyrobetaine to the bath. There is an initial quick response, resembling that caused by acetylcholine, which is sometimes followed by a slow tonic contraction which may continue for several minutes. In addition, the following difference can be observed. The contractions of the intestine induced by acetylcholine are reduced or abolished by the addition to the bath of a brain extract containing

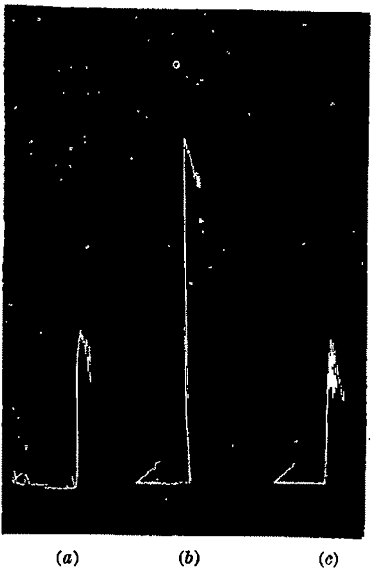

Fig. 2. The effect of γ-butyrobetaine and factor I on the isolated ileum of the guinea pig. (*a*) γ-Butyrobetaine, 5 × 10^{-8}; (*b*) γ-butyrobetaine, 5 × 10^{-8} + factor I, 0·003 units/ml. of bath fluid; (*c*) γ-butyrobetaine, 5 × 10^{-8}

an inhibitory principle (factor I)[10]. This effect is shown in Fig. 1. However, when γ-butyrobetaine and factor I are added together to the intestine bath, there is an enhancement of the contraction (Fig. 2). No evidence of an inhibitory effect of factor I on the contractions induced by γ-butyrobetaine similar to that observed with acetylcholine has ever been found. In those cases where a slow tonic contraction of the tissue succeeds the quick response, it appears that the potentiation due to factor I is confined to the fast phase[10].

Thus, although the parallelism in action between γ-butyrobetaine and acetylcholine is close, it is not entirely general. Since the relationship between acetylcholine and factor I on the ileum of the guinea pig is not entirely clear, it is not possible to comment on the difference here observed with γ-butyrobetaine. The other pharmacological actions of γ-butyrobetaine can be satisfactorily explained by a prolonged action like that of acetylcholine.

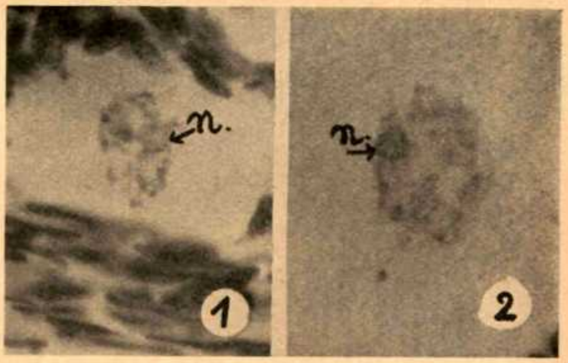
Content of Deoxyribonucleic Acid of the Germinal Vesicle of the Primary Oocyte in the Rabbit

BY means of centrifugation experiments, evidence of persistence of deoxyribonucleic acid in the growing nucleus of the primary oocyte was put forward by J. Brachet[1]. J. Govaert[2] was able to demonstrate that, in *Fasciola hepatica*, the acid not only persists but also remains quantitatively constant in the germinal vesicle. The same quantitative constancy was later found by J. Mulnard[3] to be existing in the oocytes of *Acanthoscelides obtectus*.

During our studies on content of deoxyribonucleic acid in the ovary of the rabbit, we tried to discover if this same constancy also occurs in this mammalian species. In the rabbit ovary, fixed in alcohol (75 parts), formalin (20 parts) and acetic acid (5 parts), the Feulgen reaction shows more or less visible chromosomal loops in the germinal vesicles of the oocytes, present in primary follicles (Figs. 1 and 2). This distribution, although not favourable, permits measurements by means of L. Lison's histophotometrical method[4], so that a relative amount of deoxyribonucleic acid, expressed in arbitrary units, can be obtained and compared with a standard value, given by the mean acid content of spermatocytes I measured in a rabbit testis under identical experimental conditions. The mean content of deoxyribonucleic acid for 107 measured oocytes was 2,400 ± 50·2 ($S = 523{\cdot}7$), while for 301 spermatocytes I we obtained 2,393 ± 26·8 ($S = 465{\cdot}4$).



Figs. 1 and 2. Demonstration of the youngest (1) and oldest (2) measured germinal vesicles, stained by the Feulgen reaction. Statistical computation shows that, so far as their content of deoxyribonucleic acid is concerned, the nuclei between those two limits belong to the same population (*n*, nucleolus, surrounded by a ring of nucleolus-associated chromatin)

The distribution of deoxyribonucleic acid found in those young germinal vesicles seemed to permit only the demonstration of an order of magnitude.

These results suggest that in the rabbit oocyte I, the content of deoxyribonucleic acid corresponds to the theoretically expected content (4*n*, as in the spermatocytes I). Moreover, this content remains unchanged at least during the formation of the young germinal vesicle, up to the stage measured here.

Liver Hexokinase Activity in Rats adapted to Intermittent Starvation

FÁBRY'S experiments[1] which were performed in this laboratory have shown that, in rats adapted to intermittent starvation, more glycogen is deposited in the liver after the intake of an equal amount of a mixed diet than in rats fed normally. We may thus expect that in these animals there develops an adaptation of the enzymes participating in glycogen synthesis. We have therefore attempted to estimate the liver hexokinase activity, because this enzyme has a key position in the synthesis of glycogen.

We used female Wistar rats with an initial weight of about 100 gm. During the experiment the animals were kept at a temperature of 21–23° C. During the six-week period of adaptation to intermittent starvation we interposed gradually longer fasts between the days when the animals had free access to food. During the last week of adaptation the animals were fed only twice[1]. The total food consumption in the adapted animals amounted to 60 per cent of the intake of control animals fed *ad lib.* Throughout the experimental period the animals had free access to water. The rats were fed on a stock diet (Larsen's diet) providing about 25 cal. per cent protein, 25 cal. per cent fat and 50 cal. per cent carbohydrate.

Table 1. HEXOKINASE ACTIVITY OF LIVER HOMOGENATE OF RATS ADAPTED TO INTERMITTENT STARVATION

Experimental group	No. of rats	Glucose utilized ($\gamma \pm$ S.E.)	P	Initial glycogen content ($\gamma \pm$ S.E.)	Uptake of glycogen ($\gamma \pm$ S.E.)
A. Stock diet					
Fed animals: adapted	8	25·5 ± 8·1	< 0·05	256 ± 78	75 ± 19·5
controls	6	2·9 ± 8·5		215 ± 62	55 ± 13·5
Fasted for 24 hr.: adapted	8	30·0 ± 6·0	< 0·02	34 ± 5·1	28·9 ± 7·0
controls	7	10·5 ± 6·2		23 ± 3·8	20·0 ± 3·6
Fasted for 48 hr.: adapted	7	27·0 ± 3·7	< 0·01	32·5 ± 3·9	31·6 ± 2·1
controls	6	8·5 ± 3·0		26·6 ± 6·5	23·2 ± 5·7
B. Carbohydrate-free diet					
Fasted for 24 hr.: adapted	6	10·5 ± 3·5	N.S.	21·2 ± 2·7	14·5 ± 3·2
controls	6	9·5 ± 4·4		24·2 ± 5·3	19·5 ± 3·4

The amount of homogenate used corresponded to 20 mgm. liver (wet weight). 150γ glucose was added.

Hexokinase activity was estimated in the liver homogenate, using Long's method[2] based on the disappearance of added glucose. Simultaneously, we investigated the glycogen content at the beginning and at the end of a period of incubation in trichloracetic deproteinate, using Nelson's method[3]. Because the nitrogen content of the liver, calculated on a wet-weight basis, is practically the same in animals adapted to intermittent starvation and in control animals[4], we evaluated the results on a wet-weight basis.

Enzyme activity was assessed in animals fed 10 gm. of Larsen's diet per 100 gm. body-weight (the food was consumed freely overnight) and after a 24- and a 48-hr. fast respectively. Before fasting, the rats received a weighed quantity of Larsen's diet (10 gm./100 gm. body-weight).

As can be seen from Table 1, rats adapted to intermittent starvation have a markedly increased hexokinase activity, both when satiated and while fasting, compared with normally fed controls. The uptake of added glucose, which is used as the criterion of hexokinase activity, was on average 20 per cent in these animals, while in rats fed normally it was considerably lower, even approaching zero. The small uptake of glucose in the liver homogenate of normal rats has already been recorded[2,5].

The relatively high content of glycogen in this tissue and the glycogenolysis during incubation obviously play a part in this phenomenon. In animals adapted to intermittent starvation, the glycogen content of the liver homogenate is equal to or somewhat higher than in the controls; the glycogenolysis during incubation could thus only diminish the difference between the adapted animals and controls, and have an adverse effect on our results.

In animals adapted to intermittent starvation, a marked hyperphagia develops when they have access to food[6] and the intestinal absorption of glucose is increased[7]. It is therefore possible that the increased activity of liver hexokinase was induced by the intermittently increased supply of glucose by the portal blood to the liver. We therefore adapted a further group of animals to intermittent starvation, using the same method. The Larsen stock diet was, however, replaced by a diet practically free of carbohydrate (69·9 cal. per cent protein, 29·75 cal. per cent fat and 0·75 cal. per cent carbohydrate). Despite the fact that in adapted animals even under these conditions hyperphagia developed when the animals were allowed food, we found no difference in the hexokinase activity of adapted and control animals fed *ad lib.* on the same diet after a 24-hr. fast (Table 1*B*). We can thus assume that the deciding factor for the increase of liver hexokinase, revealed in the intermittently starving animals on a mixed diet, was the intermittently increased supply of glucose absorbed by the liver during the periods of free access to food. We thus may speak of a "substrate-induced enzymatic adaptation"[8].

Granulocyte Precipitins of Human Tissues and Activated Sera

IN a preliminary communication[1] we reported that the addition of water-soluble extracts of human granulocytes to saline extracts of any other human cell resulted in the formation of a precipitate. This phenomenon can be studied by Ouchterlony's double gel diffusion method[2]. The substances giving rise to the precipitate were designated as 'granulocyte factor' and 'tissue factor'.

In the present communication it will be shown that the tissue factor exists in most human sera, including those from apparently normal subjects, but in an inactive form. Activation of this substance can be accomplished by dialysis of the sera against physiological saline.

The methods used to prepare extracts from granulocytes and other leucocytes will be presented in detail elsewhere. Human granulocytes were isolated from heparinized blood of patients with chronic myelogenous leukæmia using polyvinylpyrrolidone according to Wasastjerna's procedure[3], modified to handle large amounts of blood. Contaminating erythrocytes were removed by the addition of hypotonic saline, which lysed the red cells but not the leucocytes. The thoroughly washed cells were homogenized in ice-cold saline in a Waring blendor, and the supernate was dialysed against distilled water. After removal of the precipitate, the water-soluble fraction was lyophilized. Extracts of normal leukocytes and white cells from other forms of leukæmia were obtained in a similar manner.

The double gel diffusion method has been described[4]. All cups were filled simultaneously with 0·2 ml. of the reagents and refilled the next day with the same amount. When the extracts were used at optimal concentration, lines of precipitate could be observed within 24 hr. From Fig. 1 it can be seen that the

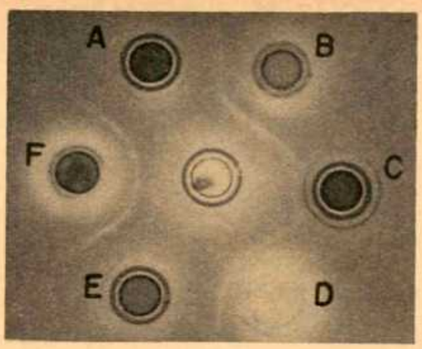

Fig. 1. Centre cup and cups *A* and *E*, extracts from granulocytes of three different patients with chronic myelogenous leukæmia. Cups *B* and *F*, extracts of leucocytes from two patients with acute leukæmia. Cup *D*, extract of leucocytes from a patient with chronic lymphocytic leukæmia. Cup *C* is empty

extracts of granulocytes did not react with each other, but that lines of precipitate were formed between the extracts of granulocytes and other leucocytes. These lines simulated immune systems in that they were dissolved if the initial concentration of one of the reagents was in excess, and they migrated away from the cup containing this reagent. The reaction is specific in that only extracts from normal or leukæmic granulocytes react with the other cell extracts. It resembles in this respect the system described by Seligmann *et al.*[5]. The tissue factor has been demonstrated in all human cells examined, including those grown in tissue culture or on the allantoic membrane of the chick embryo, indicating that it is not a serum contaminant.

No reactions were observed between extracts of granulocytes and untreated human sera. However, after dialysis against saline, most of these sera reacted in the same manner as did extracts from cells containing the tissue factor (Fig. 2). When activated sera were placed adjacent to a cup containing tissue extract, the two resulting lines of precipitate coalesced, indicating that the precipitin of the serum was the same as that of the tissues.

The fact that most human sera could be activated by dialysis suggests that they contain a substance of low molecular weight capable of inhibiting the reaction between serum tissue factor and the granulocyte factor. It is not known whether the tissue factor has a physiological function, but the presence of an inhibitor against it indicates that it may. At present we are trying to isolate and define the two precipitating factors as well as their inhibitor. This system is now also being studied in pathological sera.

Comparison of the Formation of the Complex, Sensitized Erythrocyte-Complement ($EAC'_{1,4,2}$) in Hæmolytic Systems differing in their Hæmolysin and Complement-fixing Activities

IN a recent study[1] we compared the complement fixing and hæmolytic titres of several different hæmolytic systems. We found a lack of correlation between the titres of these two activities when compared in different hæmolytic systems. In addition, we found striking differences in the quantity of complement (C') capable of being fixed by these systems. These findings indicated that C' fixation and hæmolysis represent quantitatively distinct serological properties.

The sequence of action of the C' components has been determined by Mayer and co-workers[2] for the sensitized sheep cell. The demonstration of this sequence, as well as current work[3,4] concerned with the participation of the C' components in immune hæmolysis, involves the fixation of measurable amounts of the C' components by sensitized cells (*EA*). In view of our findings we thought it would be of interest to compare the fixation of the C' components in hæmolytic systems which differ markedly in their C'-fixing activities.

As illustrated by Mayer *et al.*[2], in the Forssman antibody and sheep cell system, $EAC'_{1,4,2}$ formation may proceed at 0° C. without undergoing appreciable lysis. They have further shown that the presence of ethylenediamine tetraacetic acid prevents formation of the $EAC'_{1,4,2}$ complex by binding calcium and magnesium ions which are necessary for the formation of this complex. Employing this information, we examined the extent of $EAC'_{1,4,2}$ formation in three different hæmolytic systems according to the following procedure.

1 ml. of a serial two-fold dilution of each antiserum was placed in two series of tubes in an ice-bath. 1 ml. of a 1 : 10 dilution of whole guinea pig C' and 1·0 ml. of the standardized cell suspension were added. The tubes were incubated for 4 hr. at 0° C. with frequent mixing. Then 1·0-ml. amounts of 0·05 *M* ethylenediamine tetraacetic acid was added to one of each series of tubes to give a final concentration of 0·01 *M* in a total reaction volume of 5·0 ml. All tubes were then incubated for 30 min. at 37° C., centrifuged and the amount of lysis was determined by examining the supernatants spectro-

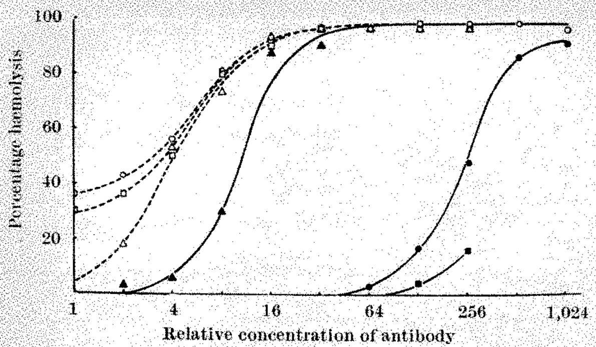

Fig. 1. The comparison of $EAC'_{1,4,2}$ formation in three hæmolytic systems. Circles, rabbit anti-sheep and sheep cells; squares, human anti-A and sheep cells; triangles, rabbit anti-human O and O cells. Open symbols, in the absence of ethylenediamine tetraacetic acid; solid symbols, in the presence of ethylenediamine tetraacetic acid

photometrically. Included were appropriate controls for: spontaneous lysis, the extent of lysis occurring during incubation at 0° C., and the effectiveness of $C'_{1,4,2}$ fixation inhibition by ethylenediamine tetraacetic acid.
